Although the preliminary response of the host is generated toward the biomaterial component of the implant, the ultimate success or failure of the device may also be influenced by the type of cell encapsulated. Early models of encapsulation were based on the theory of direct antigen presentation (see Fig. 28.1). Graft-derived antigen presenting cells (APC) complex soluble antigen with major histocompatibility molecules (MHC II) and present this complex to host T-cells. APC–T-cell contact interactions, along with costimulation, lead to graft recognition and rejection. According to this theory, physical separation of graft and host by a semipermeable membrane is adequate for maintaining graft function and viability. Immune recognition of foreign tissue is much more complex, however, and involves capture of soluble antigen and the production of chemotactic factors and cytotoxic molecules such as cytokines, antibodies, and complement proteins by the host (Tao *et al.*, 2002). If the membrane is permissive, graft-derived antigens can potentially diffuse across the semipermeable membrane and be processed and presented by host APCs. This leads to the generation of antibodies with specificity for the grafted cells. In conjunction with complement proteins and soluble

immune factors, antibodies may be able to traverse the membrane and destroy encapsulated cells. The indirect pathway just described is responsible for the failures of many allogeneic and most xenogeneic implants (Gill, 2001). Lastly, in addition to the generation of both nonspecific and specific immune responses, animal models themselves can differ in the immune reactions they initiate toward implantations of the same encapsulated cells (Gill, 2001). Larger-animal models tend to be more sensitive to the presence of foreign molecules. Scale-up from traditional rodent and other small-animal models to preclinical and clinical trials has met with much failure and disappointment (Gill, 2001).

It is important to note that pathways to biocompatibility do not equate to failure of this approach. Such pathways can be contravened by implantation of the capsule in relatively nonimmunogenic sites (vitreous fluid or SF) rather than directly into solid tissue, by the use of relatively small numbers of graft cells and by deploying allogeneic rather than xenogeneic cells (because of the known tendency of the latter to shell soluble antigens).

## V. CONCLUSION

Continuous delivery of therapeutic proteins by encapsulated cells is a promising alternative to traditional modes of treatment for many conditions, such as neurodegenerative disorders, diabetes, chronic pain, and cancer. Immunoisolation provides a method for achieving sustained release of specific proteins that target host tissue directly. Issues of toxicity and unwanted side effects that plague traditional therapeutic approaches can be circumvented by using this unique delivery system. Immune recognition of encapsulated cells is evaded by incorporating a selectively permeable membrane that acts as an immunological sieve. Semipermeable membranes are designed to block the diffusion of soluble immune molecules as well as activated immune cells. Simultaneously, bioactive molecules produced by the encapsulated cells and essential nutrients are allowed access to the host and encapsulated cells, respectively. Balance between these components results in a therapeutic system that not only can maintain delivery of bioactive molecules within the therapeutic window but may also be reactive to metabolic changes in the host. This dynamic equilibrium is the goal of immunoisulatory technology. Genetic engineering of implanted cells has led to more targeted and effective delivery. Optimization of the selective membrane remains an engineering challenge. Investigators have focused their efforts on designing hydrogel composite membranes, uniform nanoporous and micro-machined capsules, and vascularizing membranes to attain optimal cell viability and protein delivery (Risbud *et al.*, 2001; Leoni and Desai, 2001; Tao and Desai, 2003). With the advancement of genetic engineering and capsule design, immunoisolation offers the promise of biologically smart therapeutic systems that can be applied to virtually any physiological disorder.

### I. INTRODUCTION

Immunobarrier devices can be used to transplant cells to treat a variety of human diseases without requiring immunosuppressive drugs. Transplanted cells are enclosed within a material that provides protection from the immune system while allowing adequate transport of nutrients, oxygen, waste products, and therapeutic products. There are three types of immunobarrier devices: (1) intravascular, (2) extravascular macrocapsules, and (3) microcapsules. Challenges exist that prevent the widespread applications of cell encapsulation therapies: tissue supply, effective immune protection of encapsulated cells, and maintenance of cell viability posttransplantation. This chapter discusses approaches that can be used to overcome these problems and focuses specifically on the maintenance of cell viability in the treatment of type 1 diabetes. One method to enhance cell viability by increasing oxygen permeability of the encapsulating material with perfluorocarbons (PFCs) is discussed in detail, and a mathematical model is used to predict the extent of enhancement of islet viability and function.

Cell therapies have the potential to treat a large range of diseases by providing *in vivo* delivery of a required protein. A problem that complicates and restricts the use of cell therapies is that transplanted cells need to be protected from the immune system by immunosuppressive drugs. An engineering approach that addresses this problem is the use of immunobarrier devices that provide a physical barrier to protect transplanted cells from the recipient's immune system through a semipermeable membrane. Some diseases that have been investigated for treatment with immunobarrier devices are diabetes (Omer *et al.*, 2005), hemophilia (Brauker *et al.*, 1998), anemia (Schwenter *et al.*, 2004), parathyroid disease (Hasse *et al.*, 1997), chronic pain (Buchser *et al.*, 1996), Parkinson's disease (Kishima *et al.*, 2004), Huntington's disease (Bloch *et al.*, 2004), and amyotrophic lateral sclerosis (Aebischer *et al.*, 1996). An immunobarrier device can contain cells that constantly produce a therapeutic protein, as is required for the treatment of most of the diseases just listed, or for the case of diabetes treatment the cells secrete insulin in response to

**FIG. 29.1.** Essential elements of an implanted device that incorporates encapsulated cells, illustrating the case of a biohybrid artificial pancreas. Reproduced, with permission, from Colton (1995).

changes in the blood glucose level in a feedback-controlled mechanism.

The essential elements of an implanted device that incorporates encapsulated cells are shown in Fig. 29.1, which is a conceptual illustration of a biohybrid artificial pancreas. The implanted tissues are separated from the host by an immunobarrier membrane. Cells can be encapsulated at a high, tissuelike density, as illustrated in Fig. 29.1, or dispersed in an extracellular gel matrix, such as agar, alginate, or chitosan. The membrane prevents access of immune cells and prevents or minimizes access of humoral immune components but permits passage of the secreted product (insulin). At the same time there must be sufficient access to nutrients, such as glucose and oxygen, and removal of secreted metabolic waste products, such as lactic acid, carbon dioxide, and hydrogen ions. Transplanted cells must be supplied with nutrients by diffusion from the nearest blood supply, through surrounding tissue, the immunobarrier membrane, and the graft tissue itself.

This chapter focuses on the engineering challenges associated with developing immunobarrier devices and methods that are under study to circumvent the problems: (1) supply of tissue, (2) protection from immune rejection, and (3) maintenance of cell viability and function. The emphasis of the chapter is on immunobarrier devices used in transplanting islets for treatment of type 1 diabetes and specifically focuses on the challenge of maintaining cell viability and function. After describing the challenges, approaches are discussed to improve immunobarrier device designs to overcome some of these difficulties. One particular approach is described in detail: use of encapsulating materials that contain perfluorocarbons to enhance oxygen delivery and increase islet survival and function. A mathe-

matical analysis is presented to demonstrate the benefits of this approach.

The material presented here builds on previous reviews of the field since the early 1990s (Colton and Avgoustiniatos, 1991; Colton, 1995; Avgoustiniatos and Colton, 1997a; Avgoustiniatos *et al.*, 2000; Lewis and Colton, 2005). Consequently, in this chapter we focus on recently reported work.

## II. ENGINEERING CHALLENGES

### Device Designs

Immunobarrier device designs typically fall into three categories: intravascular devices, extravascular macrocapsule devices, and microcapsules (Colton and Avgoustiniatos, 1991; Colton, 1995). Intravascular devices create a vascular shunt between an artery and a vein. The device is typically made of a hollow fiber, where blood flows through the lumen and the transplanted cells are separated from the blood by an immunoisolating membrane. This device design is appealing because it brings blood into very close proximity with the transplanted tissue, which will aid in nutrient, waste, and therapeutic protein transport. However, the implantation of this device is associated with greater risks because you are disrupting the patient's vascular system, leading to a greater risk of complications. Human clinical trials of this type of device for islet transplantation were being planned when they were stopped by the FDA because of a mechanical failure of the cannula, in dogs, and have never been resumed. At this point in time this type of device is not under study.

The second device design type is the extravascular macrocapsule, which is typically a planar diffusion chamber or a hollow fiber. This type of device is typically implanted within a cavity of the body containing tissue within the device lumen surrounded by an immunoisolating membrane. Delivery of oxygen and other nutrients requires diffusion from the surrounding tissue to the device, across the device membrane, and then through the interior of the device itself to the tissue. This type of device can be limited in the amount of tissue that can be included within the device due to oxygen supply limitations. Oxygen supply limitations can be even further aggravated by overgrowth of fibrotic tissue, which is another transport barrier and which also consumes some of the oxygen that would normally be delivered to transplanted tissue (Avgoustiniatos and Colton, 1997b). Benefits of using macroencapsulation devices are that many tend to be made of materials that are very stable on implantation in the body, and if needed these types of devices can easily be retrieved because of their larger size. This type of device is under study for several applications, including diabetes (Desai *et al.*, 2004) and diseases of the central nervous system (Hauser *et al.*, 2004). Examples of materials used for macroencapsulation are polytetrafluoroethylene (Brauker *et al.*, 1995), which can be used to form

an immunoisolating membrane or an exterior vascularizing membrane, poly-ether-sulfone (Aebischer *et al.*, 1996), which is used for devices that have entered into clinical trials, alumina (La Flamme *et al.*, 2005), and nanoporous micromachined silicon-based membranes (Desai *et al.*, 2004), which can result in a more stringent control over the exact pore size of the material.

The final type of immunobarrier device is the microcapsule. Microcapsules are small spherical gels ranging in size from 200  $\mu\text{m}$  for islet conformal coatings to 2 mm for macrobeads. Microcapsules are currently being studied the most extensively for islet transplantation to treat diabetes. Each microcapsule typically contains one to two islets, and the microcapsules are most commonly transplanted into the peritoneal cavity. The peritoneal cavity is the implantation site of choice, because there is ample space for the implant and immune responses are not as high as at other implantation sites, such as the subcutaneous space. Capsules in this location may be located far away from the blood supply and therefore have very limited oxygen, which can have detrimental effects on tissue survival. The feasibility of microcapsule implantation in the liver via intraportal injection (the location and method for naked human islet transplantations) is being examined in order to enhance microcapsule proximity to the blood supply (Toso *et al.*, 2005). A drawback of the liver as a transplantation site is that there is an increased immune response, which was found to be reduced by short-term immunosuppression with gadolinium chloride, rapamycin, or tacrolimus (Toso *et al.*, 2005).

The most common choice of materials for microcapsules is alginate, a polysaccharide derived from seaweed. Alginate can be dissolved in water to form a viscous solution that, on exposure to a divalent ion (e.g., calcium or barium) or a trivalent ion (e.g., gadolinium), is transformed into a hydrogel. This very gentle gelation process is the reason for alginate's widespread use, because tissue can be encapsulated without causing damage to the cells. However, because it is a naturally derived product, its properties are batch and source dependent, and the impurities in the alginate itself can have detrimental effects on the success of immunobarrier devices involving alginate. Alginate microcapsules usually come in one of two forms: alginate alone cross-linked with barium ions (Omer *et al.*, 2005; Schneider *et al.*, 2005) or alginate cross-linked with calcium and then coated with poly-L-lysine (De Vos *et al.*, 2004) or poly-L-ornithine (Calafiore *et al.*, 2004) to form a perm-selective barrier and enhance capsule stability. Alternative materials to alginate are being developed. One promising example is a synthetic Tetronic polymer that thermally gels and chemically cross-links to form more stable gels while still maintaining gentle processing steps (Cellesi *et al.*, 2004). The capsule formation process for the Tetronic polymers is adaptable to the machinery developed for making alginate capsules (Cellesi *et al.*, 2004). An informational review on

the field of microencapsulation has been published (Orive *et al.*, 2004).

## Supply of Tissue

Tissue for cell therapy applications can be derived from three main types of sources: (1) human primary tissue, (2) primary xenogeneic tissue, and (3) cell lines. Each type of tissue has reasons why it is an attractive and an unattractive source. Allotransplantation, or use of primary human tissue, is desirable because this tissue, were it to be transplanted alone, would illicit less of an immune response than tissue derived from another animal (xenotransplantation). Therefore it should be easier to provide immunoprotection to allotransplanted tissue as compared to xenotransplanted tissue. However, the main drawback of primary human tissue is that it requires a cadaveric donor, and therefore the supply is extremely limited. Additionally, a procedure is required to isolate the tissue prior to transplantation, which can be costly and time consuming.

Some researchers are looking to use tissue derived from animal sources in immunobarrier devices. The main advantage of xenogeneic tissue is that its supply is not as limited. However, there is a risk of retroviral disease transmission, immunobarrier requirements are more stringent, and tissue isolation procedures are still required.

The final type of tissue that is under study for transplantation is cell lines, of which the supply of a particular cell type is infinite and there are no isolation requirements. Cell lines can be allogeneic or xenogeneic in nature. When immunobarrier devices are used to deliver a desired product at a continuous rate, as is typically desired for gene therapy strategies, the use of cell lines has proven to be an adequate cell source for this application, as is discussed in a review of encapsulation of genetically modified cells and their clinical applications (Hauser *et al.*, 2004). The main drawback of using cell lines for diabetes treatment is that the cell line must secrete insulin under the same feedback-control mechanisms as the islet and at the same rate. Also, in order to prevent hypoglycemia in diabetes treatments, the growth of the cell line should be arrested prior to transplantation. To date, this type of cell line has yet to be developed, although work is being done to address these issues in the hopes that a fully functional beta cell line will solve the tissue-shortage problem associated with islet transplantation and make the therapy available to all type 1 diabetic patients (Aoki *et al.*, 2005; Simpson *et al.*, 2005). Stem cells also offer great promise as an unlimited source of cells for immunobarrier devices, but a greater understanding and control of the differentiation process is required in order to generate cells with the desired phenotype for a particular application.

## Preventing Immune Rejection

Possible rejection pathways elicited by tissue in immunobarrier devices are shown in Fig. 29.2. The process may begin with diffusion across the immunobarrier of immuno-

**FIG. 29.2.** Possible pathways for immune rejection mechanisms with encapsulated cells. Reproduced, with permission, from Colton (1995).

genic tissue antigens that have been shed from the cell surface, secreted by live cells, or liberated from dead cells. Recognition and display of these antigens by host antigen-presenting cells initiate the cellular and humoral immune responses. The former response leads to the activation of cytotoxic T-cells, macrophages, and other immune cells. Preventing cells from entering the tissue compartment is easily achieved using microporous membranes. This may be the only requirement for immunoisolation of allogeneic tissue, at least for periods up to several months (Korsgren and Jansson, 1994). With xenografts it is also necessary to keep out components of the humoral immune response, which is more difficult to accomplish. Such components include cytokines and lymphokines (e.g., interleukin-1), which can have deleterious effects on  $\beta$ -cells, as well as newly formed antibodies to immunogenic antigens that have leaked across the barrier. In addition, there may be naturally occurring antibodies, most likely IgM, to cell surface antigens on xenografts. Antibodies produced during preexisting autoimmune disease, such as type 1 diabetes, might also bind to cell surface antigens. Last, macrophages and certain other immune cells can secrete low-molecular-weight reactive metabolites of oxygen and nitrogen, including free radicals, hydrogen peroxide, superoxide, and nitric oxide, which are toxic to cells in a nonspecific fashion. The extent to which these agents may play a role in causing rejection of immunoisolated tissue depends on how far they can diffuse before they are inactivated by chemical reactions. Based on diffusion and reaction parameters for nitric oxide and superoxide, the reaction-length scales for nitric oxide and superoxide in water are estimated to be on the order of 1 mm and 1  $\mu$ m, respectively (Colton, 1995). Therefore a macrophage that is at the surface of an immunoisolating device secreting these molecules will be capable of delivering nitric oxide to the encapsulated tissue but not

superoxide, for it will react away before it can diffuse far enough into the capsule to damage the tissue.

Cytotoxic events occur if antibodies and complement components pass through the membrane. Binding of the first component (C1q) to IgM or two or more IgG molecules initiates a cascade that culminates in the formation of the membrane attack complex, which can lyse a single cell. IgM (910 kDa) and C1q (410 kDa) are both larger than IgG (see Fig. 29.3), so if host IgM and C1q can be prevented from crossing the barrier, then a specific, antibody-mediated attack on the islet cell should be averted. If the alternative complement pathway is activated and not inhibited by the implanted tissue, then passage of C3 (200 kDa) across the membrane must be prevented.

The precise mechanism(s) that may play a role in rejection of encapsulated tissue are, in general, incompletely understood, and they probably depend on the specific types of cells present, the species and its phylogenetic distance from humans, and the concentration of humoral immune molecules to which the implanted tissue is exposed. The latter depends on the transport properties of the immunobarrier membrane as well as on the total mass of cells implanted (which affects the magnitude of the immune response), the tissue density, and the diffusion distances between tissue and immunobarrier membrane (which affect access of the generated humoral components to the graft tissue). If complete retention of IgG (or even C1q and IgM) coupled with passage of albumin and iron-carrying transferrin (81 kDa) is required, there is a problem because of the size discrimination properties of membranes, in which there is invariably a wide distribution of pore sizes. If cytokine transport must also be prevented, the problem is even more difficult. A comparison of molecule sizes required for cell survival, the insulin that is required to be secreted so that the device is functional, and the immune system com-

**FIG. 29.3.** Comparison of molecular weights of immune system molecules and molecules required by cells for survival. Modified from Colton (1995, Fig. 19).

ponents are shown in Fig. 29.3. This figure demonstrates that if the cells require albumin and transferrin, then the transport of cytokines to the tissue cannot be blocked by an immunobarrier alone. The membrane would have to allow for cytokine transportation but could potentially contain components that could deactivate the cytokines before they reach the encapsulated tissue. If free radicals and other reactive oxygen and nitrogen species pose a significant problem, no passive membrane barrier will be able to provide immunoprotection, and some other approach (e.g., scavenging of free radicals, immunomodulation of transplanted tissue, local suppression of host immune response) will be necessary. The portion of overgrown allotransplanted alginate-PLL microcapsules containing rat islets explanted four weeks posttransplantation were shown to have mostly macrophages, with some fibroblasts on the capsule surface, without any NK cells, granulocytes, T-cells, or B-cells (De Vos *et al.*, 2004). These results indicate that in an allotransplantation model it may be most important to block macrophage activation and neutralize the effects of nitric oxide and superoxide to prevent immune rejection.

### Maintenance of Cell Viability

Maintenance of cell viability and function is essential and is limited by the supply of nutrients and oxygen. Diffusion limitations of oxygen in tissue *in vivo* are far more severe than those of glucose because the concentration of glucose in tissue is manyfold higher (Tannock, 1972). The requirements of specific tissues for other small molecules and for large macromolecules are poorly understood or have not yet been quantified; transport limitations for large molecules are highly dependent on immunobarrier membrane properties, whereas oxygen limitations are always serious. Hypoxia at levels high enough to keep cells alive can nonetheless have deleterious effects on cell functions that require high cellular ATP concentrations—for example, ATP-dependent insulin secretion (Dionne *et al.*, 1993). Supply of oxygen to immunoisolated tissue is therefore the critical component that determines tissue survival.

Oxygen supply to encapsulated cells depends in a complicated way on a variety of factors, including (1) the site of implantation and the local oxygen partial pressure ( $P_{O_2}$ ) in the blood, (2) the spatial distribution of host blood vessels in the vicinity of the implant surface, (3) the oxygen permeability of the membrane or encapsulant, (4) the oxygen consumption rate of the encapsulated tissue, (5) the geometric characteristics of the implant device, and (6) the tissue density and spatial arrangement of the encapsulated cells or tissues. Despite encouraging results with various tissues and applications (Hauser *et al.*, 2004), the problem of oxygen transport limitations is one of the major hurdles that remain. The maximum  $P_{O_2}$  (about 40 mmHg for the microvasculature) available for extravascular devices limits the steady-state thickness of viable tissue that can be supported.

Islets are particularly prone to oxygen supply limitations because they have a relatively high oxygen consumption rate (Dionne *et al.*, 1993). In the normal physiologic state they are highly vascularized and are supplied with blood at arterial  $P_{O_2}$ . When cultured *in vitro* under ambient normoxic conditions, islets develop a necrotic core, the size of which increases with increasing islet size, as is to be expected as a result of oxygen diffusion and consumption within the islet (Dionne *et al.*, 1993). Central necrosis of the encapsulated islet occurs after islet microcapsule transplantation, resulting in reduction in transplant volume when only a small fraction (~10%) of the capsules have fibrotic overgrowth (De Vos *et al.*, 1999). The fact that necrotic tissue is at the center instead of the periphery of the islet indicates that it is likely a nutrient or oxygen supply limitation causing the necrosis and not a mechanism of the immune system. Hypoxia causes encapsulated islets in culture to become necrotic, to up-regulate iNOS (inducible nitric oxide synthase), which indicates that islets are producing NO, which can cause damage to themselves, and to up-regulate MCP-1 (monocyte chemoattractant protein 1), which can attract macrophages and hence also induce islet damage postimplantation (De Groot *et al.*, 2003). The results of all of these

studies indicate that oxygen transport limitations exist within transplanted islet microcapsules and can have serious effects on islet survival.

Previous modeling studies have investigated how device designs affect oxygen transport limitations. When comparing devices that are shaped like slabs, cylinders, or spheres, the spherical geometry is the most beneficial when comparing the volume fraction of nonanoxic tissue in each geometry (Avgoustiniatos and Colton, 1997a). When small amounts of tissue are required for transplantation, the size of the device that is required is feasible in all geometries; but as the amount of tissue increases, especially for the large amount required for islet transplantation, the surface area of the slab, the length of the cylinder, or the number of microcapsules increases significantly (Avgoustiniatos and Colton, 1997a). The size of a planar diffusion device and the volume of microcapsules needed was estimated by assuming that 500,000 islets may be required to treat type 1 diabetes (Ryan *et al.*, 2005). In a planar diffusion device with 120- $\mu\text{m}$  islets sandwiched between 100  $\mu\text{m}$  thick membranes and device surface oxygen partial pressure of 40 mmHg, the maximum islet density is 1100 islets/ $\text{cm}^2$  for fully functional tissue, which corresponds to a total device surface area of 450  $\text{cm}^2$  (Avgoustiniatos, 2001). If it is assumed that there is 1 islet/500  $\mu\text{m}$  diameter microcapsule, then 500,000 capsules would need to be transplanted, equaling a total volume of 33 mL.

### III. STRATEGIES FOR IMPROVING IMMUNOBARRIER DEVICES

#### Enhancement of Immunoprotection Capacity of Devices

It will never be possible to create a device that provides complete immunoprotection. Therefore it is most likely necessary to augment the immunoprotection by short-term administration of immunosuppressive drugs, trapping or neutralizing small toxic molecules released during an immune response, or enhancing the resistance of the islet to the stresses experienced during an immune response. Administration of immunosuppressive drugs defeats the purpose of an immunobarrier device, but tissue survival can be enhanced if immunosuppressive drugs are administered to inhibit the immune response, when it is most severe, for a short time period posttransplantation. Administration of antibody molecules that block T-cell costimulation pathways (CTLA4-Ig, anti-CD154, and anti-LFA-1) enhances the length of graft function for neonatal porcine cell clusters or adult porcine islets in alginate microcapsules (Kobayashi *et al.*, 2005; Safley *et al.*, 2005). Alternatively, in order to decrease the immune response posttransplantation, macrophage activation can be prevented by systemic administration of gadolinium chloride (Toso *et al.*, 2005) or local administration of clodronate liposomes to reduce cell overgrowth of alginate microcapsules (Omer *et al.*, 2003). These

studies demonstrate that short-term immunosuppression, which is far less risky than lifetime immunosuppression, can be beneficial in promoting graft survival and enhancing the efficacy of immunobarrier devices.

An alternative approach to suppressing the immune system to enhance graft survival is to neutralize or trap the toxic molecules of the immune system released to destroy the transplanted tissue. Macrophages play a role in immune responses to immunoisolated tissues, and it has been demonstrated that the release of nitric oxide from activated macrophages, and not cytokines, is responsible for islet destruction, in a dose-dependent manner (Wiegand *et al.*, 1993). Therefore, including a nitric oxide scavenger such as hemoglobin within the microcapsules can inhibit islet cell death through nitric oxide-mediated mechanisms. Results have shown that the inclusion of live erythrocytes, fixed erythrocytes, or cross-linked hemoglobin in alginate microcapsules enhances islet survival with exposure to activated macrophages or nitric oxide (Wiegand *et al.*, 1993; Chae *et al.*, 2004b).

#### Enhancement of Oxygen Transport to Encapsulated Tissue

In order for immunobarrier devices to be successful, the transplanted cells must remain viable and functional posttransplantation. Methods have been developed to enhance mass transfer to immunoisolated tissue, most specifically transport of oxygen, by using vascularizing membranes, *in situ* oxygen generation, and thinner microcapsules and by enhancing the oxygen-carrying capacity of immunoisolating materials. Mass transfer of oxygen to an immunoisolated device can be enhanced if the vasculature is brought in very close contact with the device. The vasculature cannot come into direct contact with the tissue itself, which would be a breach of the immunobarrier, but vessels in close proximity to the device are beneficial. The Theracyte<sup>TM</sup> (Baxter Healthcare) planar diffusion chamber has two membranes: (1) an exterior vascularizing membrane that has an optimal pore size (5  $\mu\text{m}$ ) so that cells can penetrate the layer and vascularization is induced; and (2) an immunoisolating membrane, pore size 0.45  $\mu\text{m}$ , both made from PTFE (Brauker *et al.*, 1995). The Theracyte<sup>TM</sup> device can be preimplanted in order to induce vascularization of the device prior to transplantation, which aids in islet survival posttransplantation (Rafael *et al.*, 2003). In addition, infusion of the device with VEGF (vascular endothelial growth factor) improves the density of blood vessels that form around the device (Trivedi *et al.*, 2000).

An alternative approach to overcome oxygen limitations is to supply implanted tissue with oxygen generated *in situ* adjacent to one side of the immunobarrier device (Wu *et al.*, 1999). On the other side, the exterior of the device is exposed to either culture medium for *in vitro* studies or the host tissue for *in vivo* conditions. *In situ* oxygen generation can occur by the electrolytic decomposition of water in

an electrolyzer (Wu *et al.*, 1999). The electrolyzer is in the form of a thin, multilayer sheet, within which electrolysis reactions take place on the anode and the cathode to form oxygen and hydrogen, respectively (Wu *et al.*, 1999). *In vitro* studies with  $\beta$ TC3 cells in the *in situ* oxygen generation device show that the thickness of viable tissue increases with oxygen generation (Wu *et al.*, 1999).

Oxygen transport to encapsulated islets can be enhanced by reducing the diffusion distance through the use of smaller capsules or thinner membranes. There are drawbacks to reducing the diffusion distance, because free radicals released from immune system effector cells may not become inactivated prior to reaching the encapsulated tissue, and the amount of shed antigens from the encapsulated tissue can be increased, thereby enhancing the recipient's immune response to the transplant. Alginate capsules made using an electronic droplet generator, as opposed to an air-driven droplet generator, can be made to be  $<500\text{ }\mu\text{m}$  instead of  $\sim 800\text{ }\mu\text{m}$ . There are also techniques in which only a thin coherent membrane is used to coat the islets. Examples are the use of an emulsion procedure to form calcium alginate PLO microcapsules (Leung *et al.*, 2005) or by centrifuging an islet alginate cell suspension in a discontinuous gradient that contains a barium chloride layer (Zekorn *et al.*, 1992).

A final approach that can be employed to enhance oxygen delivery to encapsulated tissue is to enhance the oxygen-carrying capacity of the material and thus increase the rate at which oxygen can be delivered to the tissue. Components that can be used for this purpose are organic compounds with high oxygen solubility, such as perfluorocarbons or silicone or soybean oils. Perfluorocarbon emulsions have been developed as blood substitutes and could be incorporated into the encapsulation material to increase its oxygen permeability. Perfluorocarbons and silicone oils have been used to enhance oxygen transfer in bioreactors (McMillan and Wang, 1990; Poncellet *et al.*, 1993). There are reports in the literature that including a perfluorocarbon emulsion in islet culture medium enhances islet function (Zekorn *et al.*, 1991). Perfluorocarbons have also been used in the storage of the pancreas prior to islet isolation, to increase islet yield and storage time (Matsumoto and Kuroda, 2002). Inclusion of hemoglobin in alginate microcapsules increases the length of islet survival after transplantation (Chae *et al.*, 2004a), but this enhancement likely results from trapping of nitric oxide.

We envision that the type of microcapsule that results in successful islet transplantation will provide some immunoprotection by preventing contact between islets and activated immune cells, complement components, and antibodies. However, this is likely not enough to provide complete immune protection, and inclusion of a costimulatory blocker such as CTLA4-Ig and an NO scavenger such as red blood cells will greatly enhance the immunoprotective properties of the microcapsules. These modifications should

help in preventing immune destruction of the islets, but increased delivery of oxygen is still required to maintain islet survival and function. Increased oxygen delivery can be accomplished by including a permeability enhancer, such as a PFC emulsion, in the alginate matrix. A picture of this ideal microcapsule that is likely to overcome many of the challenges that hamper immunobarrier devices is depicted in Fig. 29.4. The following section examines the oxygen levels within microcapsules that contain islets and a PFC emulsion for the purpose of improving islet survival and function.

## IV. THEORETICAL ANALYSIS OF PFC-CONTAINING MICROCAPSULES

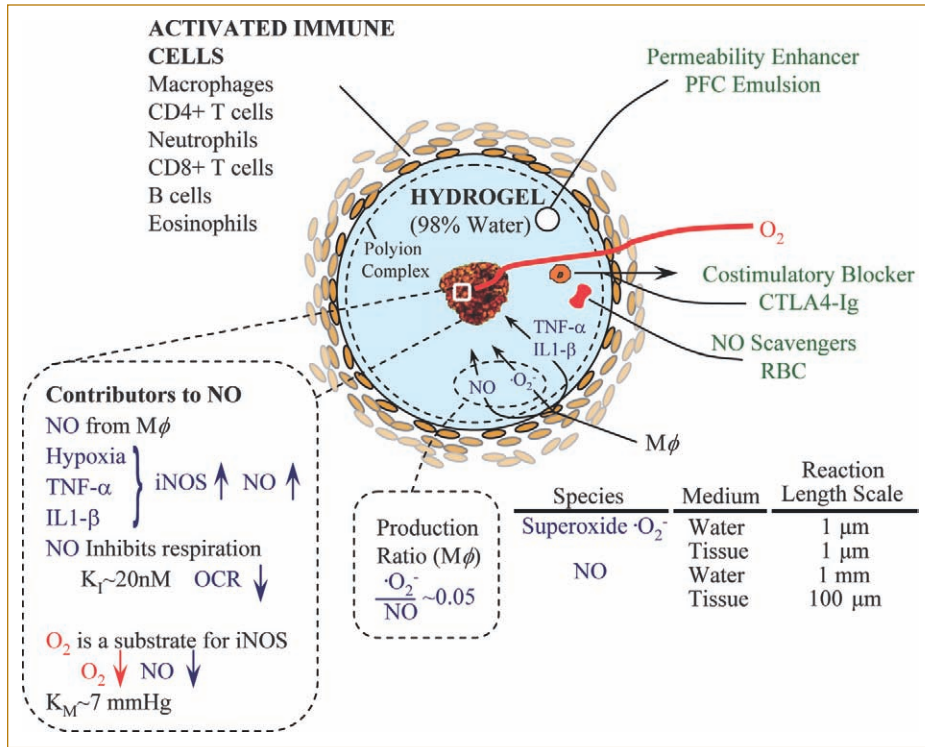

One way to enhance oxygen delivery to immunoisolated tissue is to increase the permeability of the immunobarrier material. One method to enhance the permeability of alginate microcapsules for islet transplantation is to make the capsules from an alginate solution that contains a perfluorocarbon (PFC) emulsion. Perfluorocarbons are highly desirable materials for enhancing oxygen delivery, due to their very high oxygen solubility, approximately 25 times that of water, on a volumetric basis. Enhanced solubility will lead to enhanced permeability because the permeability is the product of the gas solubility and diffusivity in the material of interest. We have currently been studying a perfluorocarbon emulsion made from perfluorodecalin and 20 wt% (w/v) Intralipid® (Baxter), a soybean oil emulsion (Schweighardt and Kayhart, 1990). To assess the benefits of PFC-containing microcapsules, a theoretical model has been developed to predict the local partial pressure of oxygen, which, in turn, is used to assess tissue viability and the fraction of normal insulin secretion for encapsulated islets and single cells. Predictions of the model will be presented for a  $500\text{-}\mu\text{m}$  capsule that contains a  $150\text{ }\mu\text{m}$  diameter islet or single cells that have a total tissue volume equal to that of the  $150\text{ }\mu\text{m}$  diameter islet. A diagram of the two geometries is presented in Fig. 29.5. The islets are assumed to have the properties of rodent islets, in which the beta cells (Layer 1), comprising about 75% of the islet volume, are at the center of the islet and the non-beta cells form an outer shell (Layer 2) that is then surrounded by the alginate microcapsule (Layer 3). It should be noted that human islet beta cells are distributed throughout the entire islet; consequently, predicted beta cell viability and insulin secretion predictions will be slightly higher than for rodent islets.

### Problem Formulation

We used the one-dimensional species conservation equation for reaction and diffusion in spherical coordinates to predict the oxygen profile within the microcapsule:

$$D_i \frac{1}{r^2} \frac{d}{dr} \left( r^2 \frac{dC_i}{dr} \right) = V_i \quad \text{Eq. (29.1)}$$

**FIG. 29.4.** Activated immune cells surround the microcapsule, causing islet damage. Immune cell types are listed roughly in decreasing order of involvement in inflammatory and immune reactions to implanted immunobarrier devices. Macrophages damage islets through the release of nitric oxide, super oxide, and cytokines (labeled in blue). Oxygen supply (labeled in red) to encapsulated islets is limited, causing hypoxic conditions that are detrimental to islet survival. Potential methods to protect tissue from immune reactions or enhance oxygen delivery to improve encapsulated islet survival are labeled in green.

**FIG. 29.5.** Capsule geometry (drawing not to scale).

where  $D_i$  ( $\text{cm}^2/\text{s}$ ) is the effective diffusivity of oxygen in layer  $i$ ,  $C_i$  ( $\text{mol}/\text{cm}^3$ ) is the concentration of oxygen in layer  $i$ , and  $V_i$  ( $\text{mol}/\text{cm}^3/\text{s}$ ) is the local oxygen consumption rate per unit volume in layer  $i$ . For convenience, since partial pressures are equal across interfaces of different materials, we make use of oxygen partial pressure instead of concentration, which are related by

$$C = \alpha P \quad \text{Eq. (29.2)}$$

where  $\alpha$  ( $\text{mol}/\text{cm}^3/\text{mmHg}$ ) is the effective Bunsen solubility coefficient in layer  $i$ , and  $P$  is the partial pressure of oxygen. Combining Eqs. (29.1) and (29.2) gives

$$(\alpha D)_i \frac{1}{r^2} \frac{d}{dr} \left( r^2 \frac{dP_i}{dr} \right) = V_i \quad \text{Eq. (29.3)}$$

The oxygen consumption rate is assumed to follow Michaelis–Menten kinetics for all tissue,

$$V_i = \frac{V_{\max} (1 - \epsilon_i) P_i}{K_m + P_i} \quad \text{Eq. (29.4)}$$

where  $V_{\max}$  is the maximum oxygen consumption rate for the tissue,  $\epsilon_i$  is the tissue volume fraction in layer  $i$ , and  $K_m$  is the Michaelis–Menten constant. For the capsule that contains an islet, no oxygen is consumed in the alginate layer; therefore  $V_3$  is equal to zero, and the tissue volume fraction in the islet (Layers 1 and 2) is equal to 1.

Equation (29.3) is solved simultaneously for the three layers of the islet microcapsule, subject to the following boundary conditions. The islet is assumed to be centrally located. At the capsule center a symmetry boundary condition is used:

$$\left. \frac{dP_i}{dr} \right|_{r=0} = 0 \quad \text{Eq. (29.5)}$$

Transport and reaction parameters in Layers 1 and 2 are identical. There is no need for a separate solution in regions 1 and 2 or for the associated boundary conditions. At the interface between Layers 2 and 3 (the interface between the non-beta-cell portion of the islet and alginate), where  $r = R_2$ ,

$$r = R_2 \quad P_2 = P_3 \quad \text{Eq. (29.6)}$$

$$r = R_2 \quad (\alpha D)_2 \frac{dP_2}{dr} = (\alpha D)_3 \frac{dP_3}{dr} \quad \text{Eq. (29.7)}$$

The final boundary condition required to solve the equations is the assumption that the external partial pressure of oxygen is specified at the capsule surface ( $P_S$ ):

$$r = R_3 \quad P_3 = P_S \quad \text{Eq. (29.8)}$$

For the case of a capsule containing dispersed single cells that have a total volume equal to a 150- $\mu\text{m}$  islet, the model consists only of one layer,  $\varepsilon = 0.027$ , the boundary conditions are represented by Eqs. (29.5) and (29.8), and all subscripts referring to layers can be dropped.

### Material and Tissue Properties

Several material properties for each layer were determined from theoretical relationships. The ratio of the effective permeability  $(\alpha D)_{\text{eff},i}$  for layer  $i$ , consisting of a dispersed ( $d$ ) phase and a continuous ( $c$ ) phase (as occurs in the alginate layers of the model system), to the permeability of the continuous phase  $(\alpha D)_c$  was calculated from Maxwell's relationship:

$$\frac{(\alpha D)_{\text{eff},i}}{(\alpha D)_c} = \frac{2 - 2\phi + \rho(1 + 2\phi)}{2 + \phi + \rho(1 - \phi)} \quad \text{Eq. (29.9)}$$

where  $\alpha D$  is the effective permeability of the material (mol/cm/mmHg/s),  $\rho = (\alpha D)_d / (\alpha D)_c$  is the ratio of the permeability of the dispersed phase to the permeability of the continuous phase, and  $\phi$  is the volume fraction of the dispersed phase. For the multiple dispersed phases employed in our model system, Maxwell's relationship was used sequentially, starting with the phase with the smallest particle size and ending with the phase with the largest particle size. For particle types of the same size, Maxwell's relationship was used for one particle and then the other (and in the reverse order), and the two results were averaged.

In the final PFC alginate composite phase, there were perfluorodecalin and soybean oil droplets of approximately the same size; the alginate polymer itself was treated as an impermeable phase dispersed in water (Fig. 29.6). The effective permeability of PFC emulsion was estimated by first using Maxwell's relationship for PFC droplets in water and then for soybean oil droplets in the PFC and water emulsion. Secondly, Maxwell's relationship was used for soybean oil droplets in water and then for PFC droplets in the soybean oil and water emulsion. The two effective permeabilities as calculated were averaged (Fig. 29.7). Finally, the effective

**FIG. 29.6.** PFC alginate consists of PFC and soybean oil droplets surrounded by an alginate matrix with a continuous water phase.

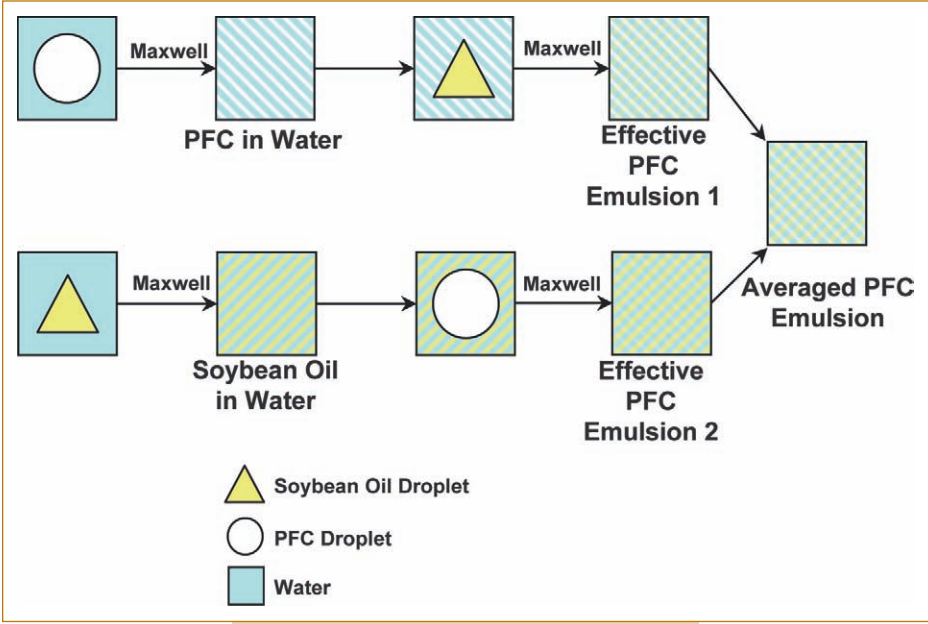

permeability of PFC alginate was estimated with alginate as the dispersed phase and PFC emulsion as the continuous phase. The pure component material transport properties are given in Table 29.1, and the effective properties for different alginate types are given in Table 29.2.

The enhancement of PFC emulsion permeability relative to that of water or to the Intralipid® emulsion used as the starting material is shown in Fig. 29.8. A 70 wt% PFC emulsion has approximately 2.8 times the permeability of water and 2.1 times the permeability of Intralipid®. There is a smaller relative enhancement in the permeability of the emulsion when compared to Intralipid® because Intralipid® contains soybean oil, which has an enhanced permeability to oxygen as compared to water. In comparison, a 90 wt% PFC emulsion (maximum PFC loading in our experimental system) has 3.6 times the permeability of water, and a 110 wt% PFC emulsion (maximum reported loading for a PFC emulsion in the literature) has 4.6 times the permeability of water.

The relationship used to predict the local fraction ( $F_S$ ) of normal insulin secretion rate as a function of local oxygen partial pressure within the islet was developed from data on the effect of hypoxia on islet insulin secretion, estimating the oxygen partial pressure profile within the islet in the experimental system, and then determining the simplest model type and parameters(s) that best predict the insulin secretion level (Dionne *et al.*, 1993; Avgoustiniatos, 2001). The result for a value of  $V_{\text{max}} = 4 \times 10^{-8}$  mol/cm<sup>3</sup>/s is

$$\begin{aligned} P < 5.1 \text{ mmHg} & \quad F_S = \frac{P}{5.1} \\ P \geq \text{mmHg} & \quad F_S = 1.0 \end{aligned} \quad \text{Eq. (29.10)}$$

The fraction of normal insulin secretion averaged over the whole islet was determined by evaluating the volume integral of  $F_S$  in Layer 1. The fractional viability of the beta cell

core (Layer 1) was estimated by determining the volume of tissue where  $P_1 > P_C$ .  $P_C$  is the critical oxygen partial pressure below which tissue dies, and the value of  $P_C$  is assumed to be 0.1 mmHg.

**Comparison of O<sub>2</sub> Profiles in Microcapsules Containing Single Cells or an Islet**

The model equations were solved using the parameters given in Tables 29.1, 29.2, and 29.3. The resulting oxygen profiles for a surface oxygen partial pressure ( $P_s$ ) of 36 mmHg are given in Fig. 29.9. The results demonstrate that for the same amount of total tissue, its distribution within the capsule can greatly affect tissue survival and the minimum oxygen level that the tissue experiences. In a pure-alginate capsule, the oxygen partial pressure drop from the capsule surface to its center is only 3 mmHg for dispersed cells, whereas  $P$  decreases to values equal to  $P_C$  for a capsule containing one islet in the center, thereby indicating that there will be some loss of islet tissue in the pure-alginate capsule. When the alginate microcapsule is made from a perfluoro-

### Predicted Fractional Viability and Insulin Secretion Rate

By using the oxygen profiles shown in Fig. 29.9, the overall tissue fractional viability and insulin secretion rate were calculated for the capsules containing an islet. Comparison of beta cell fractional viability and relative insulin secretion for an islet centrally located in microcapsules containing 0, 30, 70, and 110 wt% PFC–alginate microcapsules are shown in Figs. 29.10 and 29.11, respectively. The range in capsule surface oxygen partial pressure ( $P_s$ ) studied corresponds to the ranges that could occur in the peritoneal cavity, the most common implantation site of microcapsules. Experimental measurements of  $P_{\text{O}_2}$  in empty perfluorocarbon-loaded capsules have resulted in measurements ranging from 38 to

**FIG. 29.11.** Predicted fraction of normal insulin secretion for a centrally located islet in pure- and PFC-containing alginate microcapsules with variable PFC loading.  $\text{PFC wt\%} = \rho_{\text{PFC}} \times \text{PFC vol\%}$ .

0 mmHg (Zimmermann *et al.*, 2000). Over a range of  $P_s$  there is an enhancement of beta cell survival for islets encapsulated in PFC-containing microcapsules, and the degree of enhancement is a function of PFC loading. Maintenance of normal insulin secretion of islet beta cells is substantially enhanced by including PFC in the microcapsules in a dose-dependent fashion (Fig. 29.11). The results in Figs. 29.10 and 29.11 demonstrate that including PFCs in alginate microcapsules can increase islet survival and even further enhance islet function after capsule transplantation.

## V. FUTURE DIRECTIONS

Immunobarrier devices have the potential to provide treatments for many human diseases. Immunobarrier devices have entered into clinical trials in which transplantation of smaller numbers of cells or placement in less immune responsive sites is possible or even desirable, and recently a clinical trial with islet containing alginate microcapsules has begun (Hauser *et al.*, 2004; Calafiore *et al.*, 2006). No encapsulation method has yet come into widespread clinical use. Through studies of new immunobarrier materials, methods to enhance the immunoprotection properties of the materials used as immunobarriers, and methods to increase the oxygen supply to the encapsulated tissue, many human diseases, including type 1 diabetes, may one day be treated by cell therapies using immunobarrier devices.

### I. INTRODUCTION

Embryonic stem cells (ESC) are derived from human preimplantation embryos formed during infertility treatment of couples for *in vitro* fertilization (IVF). They are donated by the couples, with informed consent, for research on embryonic stem cells. In addition, couples having treatment for preimplantation genetic diagnosis (PGD) of their embryos, to avoid the birth of babies with severe genetic disease, may consent to provide their discarded early-cleavage-stage embryos for derivation of disease-specific ESC, such as those with Huntington's disease, thalassaemia, or cystic fibrosis. These ESC may be renewed *in vitro* and expanded indefinitely by regular passage in coculture with a wide range of feeder cells (e.g., mouse or human embryonic fibroblasts) and, more recently, in feeder- and serum-free culture conditions in the presence of fibroblast growth factor (FGF) and neurotrophic growth factors (NGFs). It is now strongly recommended that regular assays of karyotypic normality and the absence of genetic deletions be undertaken prior to experiments, to confirm the genomic type and normality of the ESC being studied. It is also possible to introduce reporter genes in a targeted manner into

regulatory sequences of genes of interest for ESC renewal and differentiation. ESC are pluripotential and immortal, so they can potentially form very large numbers of cells of all the tissues of the body. They may be directed into a wide range of specific mature cell types and may be selected for specific lineages under differentiating conditions by immunohistochemistry, expression of marker genes, and cell morphology. These cell types can be purified by fluorescence-activated cell sorting (FACS) and shown to be functional by biological assays *in vitro* and by transplantation into preclinical animal models of human diseases. There is considerable optimism that ESC will be used for cell therapy, as vehicles for gene therapy, targets for drug discovery, and cells for tissue engineering, in the wide spectrum of human regenerative medicine.

Embryonic stem cells (ESC) are derived from the inner cell mass (ICM) of the developing blastocyst stage embryos five to eight days after fertilization. ESC are capable of unlimited expansion *in vitro* and are considered an immortal epiblast derivative that can be maintained at a natural checkpoint in differentiation and expanded as undifferentiated colonies in the presence of appropriate feeder cells.

They can be maintained in this pluripotent phenotype indefinitely. When allowed to overgrow in culture or when grown in the absence of feeder cells, ESC will spontaneously differentiate as flat colonies in adherence cultures or as embryoid bodies, under nonadherent conditions, to produce a wide range of cell types representing ectoderm, mesoderm, and endoderm derivatives (Trounson, 2006). It has been difficult genetically to manipulate ESC, particularly for targeted mutagenesis because of the need to maintain minimal cell colonies of >10 cells. This interferes with the ability for selection to targeted transfection events, such as the introduction of antibiotic resistance, and with the clonal expansion of cells for identification of homologous recombination events. However, rapid progress has been made recently for targeting genes of interest with fluorescent marker constructs and the long-term inhibition of gene action using short hairpin RNAs (shRNAs).

## II. DERIVATION OF HUMAN EMBRYONIC STEM CELLS (hESC)

Human embryos are usually eight cells surrounded by an acellular glycoprotein shell (zona pellucida) at three days in culture *in vitro* after insemination with sperm. They form a compacted grapelike cluster of 16–32 cells on the fourth day known as a *morula*. By the fifth to sixth day the embryo is a hollow ball of >64 cells, known as a *blastocyst*, that has an outer layer of trophoblast cells and a cluster of ~10–30 internalized cells, termed the *inner cell mass* (ICM), within a fluid-filled cavity (blastocoel) (Jones, 2000; Jones *et al.*, 2002). Embryos are donated by patients treated by IVF who have consented to donate their spare embryos for research. The embryos are usually frozen and need to be thawed and grown to the blastocyst stage *in vitro*.

ESC are formed by the culture of ICM cell colonies on confluent cultures of embryonic fibroblasts inactivated by irradiation or mitomycin C (Reubinoff *et al.*, 2000; Thomson *et al.*, 1998). They may also be derived from the earlier-morula-stage embryos (Verlinsky *et al.*, 2005). There appears to be very little difference in the efficiency of producing hESC from these different stages of development. Mouse ESC may be maintained in the presence of leukaemia-inhibiting factor (LIF) in culture *in vitro* without feeder cell support. Unlike mouse ESC renewal, which is dependent on activation of the JAK-STAT pathway, human ESC cannot be maintained undifferentiated in the presence of LIF without feeders (Daheron *et al.*, 2004; Trounson, 2001b). The conventional methods used for hESC derivation were described by Thomson *et al.* (1998), Reubinoff *et al.* (2000), and others (Cowan *et al.*, 2004; Hovatta *et al.*, 2003; Mitalipova *et al.*, 2003; J. H. Park *et al.*, 2003; Stojkovic *et al.*, 2004a). It involves the isolation of ICM colonies from human blastocysts by immunosurgery or dissection and their coculture with mitotically inactivated murine or embryonic fibroblasts (MEFs) or selected human cell lines. They form typical colo-

nies of undifferentiated cells that need to be passaged weekly, or more often, as mechanically dissected colonies of >10 cells. These methods were based on those used to derive rhesus monkey and marmoset ESC (Thomson *et al.*, 1995, 1996). Many hundreds of human ESC have now been derived [*Nature News* (2006) 442, 336–337] using a variety of methods, which include the preference for microdissection of ICMs, use of entirely humanized reagents, selected human feeder cells, and derivation in specialized facilities for “Good Manufacturing or Laboratory Practice.”

It is generally considered that ESC are an epiblast derivative or even a type of germ stem cell (Zwaka and Thomson, 2005) that can be maintained in the presence of basic fibroblast growth factor (bFGF) as an immortal and pluripotent cell type under strict culture conditions. Self-renewal of ESC involves the Wnt family signaling pathway (Sato *et al.*, 2004). Recently it has been shown that ESC have tyrosine receptor kinase (TRK) family receptors, which are responsive to brain-derived neurotrophic factor (BDNF), neurotrophin 3 (NT3), and neurotrophin 4 (NT4) (Pyle *et al.*, 2006). The presence of these neurotrophins in culture medium for ESC reduces apoptosis, stabilizes chromosome ploidy during high-throughput passaging, and enables single-cell clonal derivation of ESC in coculture and feeder-free conditions.

## III. SELECTING EMBRYOS FOR PRODUCING EMBRYONIC STEM CELLS

The criteria for choosing human embryos for deriving hESCs will determine the eventual success rates for their production. In parallel to their developmental potential, it is more efficient to derive ESC from fresh, nonfrozen, rather than frozen-thawed, embryos. Twelve selected fresh blastocyst-stage embryos, grown in coculture with human fallopian tube epithelial cells, were used by us (Reubinoff *et al.*, 2000; Trounson, 2001a) to produce six ESC lines, after preliminary experiments involving around 30 embryos. This was a very high success rate when compared with much larger numbers of frozen embryos (blastocysts) commonly used to derive ESC, donated by patients who have finished their IVF treatments (Hoffman and Carpenter, 2005). Mosaic human blastocysts have been constructed by aggregating uninuclear cells of poor-quality embryos that would normally be discarded because they lack developmental potential (Alikani and Willadsen, 2002). However, the genomic variation of such mosaic embryos would limit their usefulness as ESC. There are new ESC lines now available from a variety of mutant and chromosomally abnormal embryos that are identified by PGD (Pickering *et al.*, 2005; Verlinsky *et al.*, 2005). This includes ESC for Huntington’s disease, cystic fibrosis, thalassaemia, Fanconi anaemia A, fragile X (FRMI gene), and Duchenne muscular dystrophy. These ESC are being studied for their differentiation *in vitro* and function *in vitro* and *in vivo* and for the screening of molec-

ular libraries for candidate drugs that may interfere with expression of the disease phenotype.

#### IV. MAINTAINING EMBRYONIC STEM CELLS

The long-term stability of ESC is an important issue. While normal karyotypes can be maintained for extended culture times *in vitro* (Buzzard *et al.*, 2004; Rosler *et al.*, 2004), others have reported instability of chromosomes 12 and 17 in conditions that are known to stress ESC (Brimble *et al.*, 2004; Draper *et al.*, 2004). Interestingly, Pyle *et al.* (2006) showed that NT3 and the neurotrophin receptor p75<sup>NGFR</sup> are encoded on chromosomes 12 and 17, and chromosomal amplification may enable a selective advantage of these cells in culture. The addition of neurotrophins to culture media will apparently minimize these selective pressures. It is important to reassess karyotypes regularly for ESC, particularly those passaged by enzymatic digestion into single-cell suspensions because they may continue to express pluripotent markers even when they have become aneuploid. It is also possible that microdeletions will appear after long-term culture, and it is recommended that regular screening by techniques such as comparative genome hybridization (CGH) be introduced for quality control. Similarly, there may be a need to monitor for mutations and epigenetic changes (Rugg-Gunn *et al.*, 2005) that might appear in critical genes, such as the oncogene family, which may influence differentiation and tumor formation.

Optimizing culture conditions for ESC is extremely important and is discussed in considerable detail by Hoffman and Carpenter (2005). It is likely that there will be a change to the production of hESC under the rigid regulations involved in good manufacturing practice (GMP). Completely humanized culture and preparation methods will have to be developed that involve no animal products. Bulk cultures are still in their infancy, and much work is needed to improve the systems for the optimal production of ESC and their derivatives.

Normally, blastocyst-stage embryos (Jones, 2000) are chosen for derivation of hESC, having well-developed ICMs that are isolated mechanically or by immunosurgery (Hovatta *et al.*, 2003; Mitalipova *et al.*, 2003; J. H. Park *et al.*, 2003; Reubinoff *et al.*, 2000; Richards *et al.*, 2002; Stojkovic *et al.*, 2004a; Thomson *et al.*, 1998). ICMs will form rounded cell colonies of small, tightly packed cells with a large nucleus-to-cytoplasmic ratio (Sathananthan, 2003). Serum-free culture systems containing serum substitutes and bFGF-2 may be used for propagation of hESC and reduced spontaneous differentiation. Amit *et al.* (2000) showed that hESC can be maintained in medium containing serum replacement, bFGF-2, transforming growth factor- $\beta$  (TGF- $\beta$ ), LIF, and fibronectin extracellular matrix. Pebay *et al.* (2005) have demonstrated that sphingosine-1-phosphate and platelet-derived growth factor (PDGF) are active serum

components that can replace the need to use serum for hESC culture. These data show that signaling pathways for hESC renewal are activated by tyrosine kinases synergistically with those downstream from lysophospholipid (LPL) receptors.

#### V. PLURIPOTENTIAL MARKERS OF EMBRYONIC STEM CELLS

Using microarrays, Sperger *et al.* (2003) showed the genes *POU5F1* (*Oct4*) and *FLJ10713* [a homolog highly expressed in mouse ESC (Ramalho-Santos *et al.*, 2002)] are highly expressed in both the pluripotent human ESC and embryonal carcinoma cells (ECC) and in seminomas. Others that have been identified include a DNA methylase (*DNMT3B*), which functions in early embryogenesis (Watanabe *et al.*, 2002), and *FOXD3*, a forkhead family transcription factor that interacts with *Oct4*, which is essential for the maintenance of mouse primitive ectoderm (Hanna *et al.*, 2002). *Sox2* is also highly expressed in ESC and is known to be important in pluripotentiality (Avilion *et al.*, 2003). Serial analysis of gene expression (SAGE) has been reported by Richards *et al.* (2004) and compared with some cancer SAGE libraries. As expected, *Oct4*, *Nanog*, and *Sox2* transcripts appear abundantly, but there were differences between hESC in some other transcript abundance (e.g., *Rex-1*).

Markers that are now recognized as important for pluripotentiality of ESCs include *Oct4*, *Nanog*, *Sox2*, *Foxd3*, *Rex1*, and *UTF1* transcription factors; *TERF1*, *CHK2*, and *DNMT3* DNA modifiers; *GFA1* surface marker; *GDF3* growth factor; *TDGF1* receptor; and *Stella* and *FLJ10713* (Pera and Trounson, 2004a).

For characterization of hESC it is common to report one or more of the following: *Oct4* expression, alkaline phosphatase, and telomerase activities; stage-specific embryonic antigens (SSEA)-3 and -4; hESC antigens TRA-1-60, TRA-1-81, GCTM-2, TG-30, and TG-343; and CD9, Thy1, and major histocompatibility complex class 1 (Stojkovic *et al.*, 2004b). It is important to recognize the heterogeneity of cells positive for different markers in ESC colonies. For example, only a minority of cells that are positive for GCTM-2 and negative for TG-30 express *Oct4* protein, whereas the majority of GCTM-2- and TG-30-positive cells do.

Other stem cell antigens are also sometimes reported, e.g., AC133, c-kit (CD117), and flt3 (CD135), but these are frequently only expressed in a proportion of the hESC population, making them potential derivatives of interest in the heterogeneous hESC cell population [see the discussion in the review by Hoffman and Carpenter (2005)]. The presence of *Oct4* expression alone may be misleading, for this transcription factor takes some time to shut down RNA transcription in differentiating hESC, and it is also found in other pluripotent cell populations (e.g., embryonic germ stem cells) as well as in some adult and fetal multipotential

stem cells. Target genes of *Oct4* include *Rex-1*, *Lefy-1*, *PDG-FalfaR*, and *Utf-1*, and those cooperating with *Oct4* include *Sox2* (Hoffman and Carpenter, 2005).

## VI. GENETIC MANIPULATION OF EMBRYONIC STEM CELLS

The therapeutic potential of ESC for regenerative medicine will depend on their ability to direct their differentiation into cell lineages and pure homogeneous progenitor cell types that can be screened for drug discovery, their reliance that they will remain of the tissue type required and not form undesirable teratomas or other tissue derivatives (Brustle *et al.*, 1997; Deacon *et al.*, 1998). It is often difficult to identify and monitor the appearance of specific cell types in culture, because the changes in gene expression may not be visibly identifiable or the cell morphology may not be easily recognizable, especially during the early stages of differentiation. Current methods of identification rely on tedious and time-consuming immunological methods and reverse transcriptase polymerase chain reaction (rtPCR) to detect expression of a specific marker. If the ESC derivatives of interest are to be used for transplantation studies, it is desirable to be able to separate them from the mixed population of cells.

Clonal derivation of ESC is difficult, and hence the efficiency of identifying homologous recombination for gene “knock-in” or “knockout” has been extremely low. Recently, these methods have been improved so that new ESC with fluorescent gene tags are becoming available for genes of interest in differentiation (A. Giudice and A. Trounson, submitted for publication). It is possible to transfect ESC by random integration with suitably designed DNA constructs. This can enable the determination of the role of up-regulation of transcription factors for the renewal and differentiation of ESC, identification of specific gene expression by reporter genes that enable purification of cells of interest in differentiation, and the tracking of hESC derivatives in mixed cultures or when transplanted into animal models of human disease and injury. Conventional transfection methods have been successful (Eiges *et al.*, 2001), as have lentiviral methods (Gropp *et al.*, 2003; Ma *et al.*, 2003). Zwaka and Thomson (2005) have shown that it is possible to electroporate ESC to achieve homologous recombination of ESC colony fragments. Gene function may be more appropriately determined in ESC by using small inhibitory RNAs (siRNA) (Vallier *et al.*, 2004) to explore renewal, differentiation, apoptosis, oncogenesis, etc. (Trounson, 2006).

## VII. DIFFERENTIATION OF EMBRYONIC STEM CELLS

Early morphological differentiation events may be observed in the cells within ESC colonies within a week of passage (Sathananthan *et al.*, 2002) and, together with het-

erogeneity in pluripotential markers (e.g., *Oct4* expression), can be observed in early differentiating hESC colonies. When hESC are permitted to overgrow in two-dimensional culture, cells begin to pile up, and differentiation begins at the leading-edge borders of the colony and also in the central piled-up areas of cells (Sathananthan *et al.*, 2002). A wide range of differentiating cell types can be observed in these flat cultures, including ectodermal neuroectoderm, mesodermal muscle, and endodermal organ tissue types (Conley *et al.*, 2004; Reubinoff *et al.*, 2000; Sathananthan and Trounson, 2005).

ESC may also be differentiated in three-dimensional cultures of “hanging drops” of culture medium or in plastic culture dishes, which do not favor attachment. The ESC ball up into embryoid bodies, with differentiation occurring within five to seven days into the primary embryonic germ lineages (Itskovitz-Eldor *et al.*, 2000). Human embryoid bodies have a consistent vesicular appearance and structure (Conley *et al.*, 2004; Gertow *et al.*, 2004; Sathananthan, 2003), with a variety of cell types that appear to develop in a more random organization than mouse embryoid bodies. Visceral endoderm is consistently identified in the outer layers of human embryoid bodies. With a wide variety of cell types produced in embryoid bodies, it is possible to select specific cell populations of interest in single cells using cell surface markers and cell separation techniques, including FACS of cell suspensions (Levenberg *et al.*, 2002). It is also possible to use lineage-specific promoters driving reporter genes [(e.g., transfection of the Tet-off system for driving the *pdx-1* gene in mouse ESCs (Miyazaki *et al.*, 2004)] or selective cell morphology (Reubinoff *et al.*, 2001). Cultures have also been significantly enriched for ESC-derived cardiomyocytes, using buoyant density gradient separation methods and marker selection (Kehat *et al.*, 2001; Xu *et al.*, 2002).

When ESC (>1000 cells) are transplanted into animal tissues, they form solid teratomas of advanced development and mixed tissue lineage. The tissues that are recognized are often primitive but well-organized examples of embryonic or fetal organs. Normally ESC are transplanted under the kidney or testis capsule and recovered within one to six weeks for histological examination. The teratomas contain mouse microstructures with differentiating histotypic human tissue (Gertow *et al.*, 2004).

Blood islands appear in spontaneously differentiating ESC (Sathananthan and Trounson, 2005) and hematopoietic cells formed from ESCs *in vitro* (Kaufman *et al.*, 2001). By exposing embryoid bodies to a cocktail of hematopoietic cytokines and BMP-4, Chadwick *et al.* (2003) induced the formation of hematopoietic progenitors that could produce both erythroid and myeloid derivatives. The progenitors had an immunophenotype similar to hematopoietic progenitors of the dorsal aorta. The growth factors used were stem cell factor (SCF), interleukins-3 and -6 (IL-3, IL-6), granulocyte colony-stimulating factor (GCSF), and Flt-3 ligand. Enhancement of erythroid colony formation can be

obtained with the addition of vascular endothelial growth factor-A (VEGF-A) to cultures (Cerdan *et al.*, 2004; Ng *et al.*, 2005b). A novel aggregation method has been described by Ng *et al.* (2005a) that results in the sequential expression of *Mixl1* and *Brachyury* (primitive streak markers) and *Flk1/KDR* (mesoderm marker), maturing to hematopoietic precursors at a rate of 1:500 ESC.

Selection of differentiating cells of the endodermal lineage has been difficult because of the lack of suitable selection markers of early endoderm progenitors. There is much interest in the production of pancreatic  $\beta$ -islet cells because of the potential to treat diabetes. Some cells of embryoid bodies will stain positive to insulin antibodies (Assady *et al.*, 2001; Segev *et al.*, 2004). But while they weakly express insulin-2, they do not express insulin-1 and do not stain for C-peptide, and it is probable that the insulin-positive cells are a result of the uptake up of exogenous insulin from the culture medium (Rajagopal *et al.*, 2003).

Rambhatla *et al.* (2003) reported differentiation of hESC into cells expressing markers of hepatocytes (albumin, alpha-1-antitrypsin, cytokeratin 8 and 18), which accumulate glycogen, by treatment of differentiating embryoid bodies with sodium butyrate or adherent hESC cultures with dimethyl sulfoxide followed by sodium butyrate. Others have reported hepatic-like endodermal cells in embryoid bodies (Lavon *et al.*, 2004).

## VIII. DIRECTING DIFFERENTIATION OF EMBRYONIC STEM CELLS

The enhancement of differentiation toward a specific lineage can be achieved by activating endogenous transcription factors, by transfection of ESC with ubiquitously expressing transcription factors, by exposure of ESC to selected growth factors, or by coculture of ESC with cell types capable of lineage induction (Lavon and Benvenisty, 2003; Pera and Trounson, 2004; Trounson, 2005a, 2005b). ESC may be induced to form cell types of interest by a combination of growth factors and/or their antagonists (Loebel *et al.*, 2003).

The formation of ectodermal derivatives is very common in spontaneously differentiating hESC (Reubinoff *et al.*, 2001, 2000; Sathananthan and Trounson, 2005), and this is commonly considered a developmental default pathway. The neural differentiating pathway can be enhanced in cultures (Carpenter *et al.*, 2001) and the neural progenitors transplanted into the ventricular spaces in the brain of newborn mice, resulting in diffuse migration of human neurones and astrocytes into the parenchyma and the olfactory rostral migratory pathway (Reubinoff *et al.*, 2001; Zhang *et al.*, 2001). ESC-derived neurones respond to neurotransmitters, generate action potentials, and make functional synapses (Carpenter *et al.*, 2001). Oligodendrocytes derived from ESC are able to remyelinate neurones of the shiver mouse model (Nistor *et al.*, 2005). Doperminergic neurones

can be formed from ESC (S. Park *et al.*, 2004; Perrier *et al.*, 2004), and these are of interest in preclinical transplantation experiments, where they are shown to be capable of reversing some motor behavioral abnormalities after transplantation into the brain of a parkinsonian rat model (Ben-Hur *et al.*, 2004).

ESC may be efficiently directed into neuroectoderm by culture in the presence of an antagonist to BMP signaling. Noggin blocks the BMP2 paracrine loop that drives hESC into flattened epithelial-expressing genes characteristic of extraembryonic endoderm. The “noggin colonies” are capable of renewal in culture as relatively homogeneous colonies of neuroectoderm and show facile conversion to neurones or glia in the appropriate culture systems (Pera *et al.*, 2004).

## IX. COCULTURE SYSTEMS FOR DIRECTED DIFFERENTIATION OF EMBRYONIC STEM CELLS

Coculture of monkey ESC with the rodent PA6 stromal cell line that produces stromal cell-derived inducing activity (SDIA) will result in midbrain neuronal cells that are tyrosine hydrolase positive (TH<sup>+</sup>) and express *nurr1* and *LMX1b* genes (Kawasaki *et al.*, 2002). Manipulation of culture conditions with BMP4 induces epidermogenesis or neural crest and dorsal most central nervous system cells, and suppression of *sonic hedgehog* promotes motor neurone formation (Mizuseki *et al.*, 2003; Trounson, 2004).

Mummery *et al.* (2003, 2002) have shown that cultures of ESC cultured together with mouse visceral endoderm cell type END-2 will preferentially form beating heart muscle cell colonies. These cells express the cardiomyocyte markers, including alpha-myosin heavy chain, cardiac troponins, and atrial natriuretic factor, as well as transcription factors typical of cardiomyocytes (e.g., Nkx2.5, GATA4, and MEF3) (Kehat *et al.*, 2001; Mummery *et al.*, 2002; Xu *et al.*, 2002). These cells respond to pharmacological stimuli, and the action potentials of the muscle cells produced in this coculture system most commonly resemble that for human fetal left ventricular cardiomyocytes (He *et al.*, 2003; Mummery *et al.*, 2003). Atrial- and pacemaker-like cells may also be formed in the differentiating ESC cultures. These differentiated cardiomyocytes are capable of functionally integrating into rodent heart muscle when transplanted. The human cardiomyocytes form gap junctions with mouse adult cardiomyocytes (Hassink *et al.*, 2003; Kehat *et al.*, 2004; Xue *et al.*, 2005).

Differentiation strategies similar to those developed by Lumelsky *et al.* (2001), Rajagopal *et al.* (2003), and Sipione *et al.* (2004) in mouse ESC to produce insulin and C-peptide-expressing cells have differentiated human ESC into insulin-producing cells that coexpress insulin and C-peptide and glucagon or somatostatin (Segev *et al.*, 2004). They also expressed a number of pancreatic genes that appear to be

similar to immature pancreatic beta-islet cells. In another study, reported by Brolen *et al.* (2005), human ESC allowed to differentiate spontaneously in prolonged (34-day) adherent two-dimensional cultures on mitotically inactivated MEFs, produced a heterogeneous population of cells at 14–19 days, some of which expressed Pdx-1, Foxa2, and Isl1. These cells did not produce insulin. These regions of the cultured ESC were mechanically dissected and transplanted together with dorsal pancreases of E11.5 or E13.5 mouse embryos beneath the kidney capsule of severe combined immunodeficient (SCID) mice for eight weeks. Insulin-positive human cells were organized into isletlike 5- to 25-cell clusters. These insulin-positive cells coexpressed pro-insulin and C-peptide and the key beta-cell transcription factors Foxa2, Pdx-1, and Isl1. No insulin-positive cells were found if the mouse embryonic tissue was not cotransplanted, but glucagon-positive and amylase-positive cells (but not insulin-positive cells) of ESC origin were found localized in ducts when ESC were transferred alone. These data indicate that instruction on the maturation of pancreatic islet cells may need to include components of the embryonic foregut mesenchyme in a manner analogous to that observed for ESC differentiated into mature functional human prostate tissue (Taylor *et al.*, 2006).

## X. CONCLUDING COMMENTS

Pluripotential embryonic stem cells provide a rich source of research opportunities to determine the primary nature of stemness characteristics, such as renewal and differentiation. It is clear that they are a source of a very wide range of progenitor and mature cell types, which can be used to explore differentiation pathways and what may be wrong. They will be used to study the cancer stem cell phe-

notype, and disease specific ESC will become the basic resource for determining early events that may indicate when disease phenotype will occur. This may enable early diagnostics to be developed for very serious genetic diseases and other complex diseases for which the causes remain obscure. The possible derivation of ESC from cancer cells and those from patients with degenerative tissue pathologies such as motor neurone disease, Alzheimer's disease, and muscular dystrophies may require nuclear transfer to merge diseased cells with enucleated human oocytes. While we await the developments necessary for this method in the human, it is already apparent that ESC can be derived from parthenogenetic activation of oocytes from patients with such disorders.

The rich research resource offered by the range of ESC developing will enable scientists to dissect the developmental events underpinning normal organ formation and the complex interaction of the transcriptome with the cell and matrix compartments to enable tissue formation and function. The control of cell and tissue maturation involves epigenetic regulation of gene expression, microRNAs that regulate translation and the proteomic profile. We have hardly scratched the surface of these dimensions of cell regeneration or of the obvious instruction of cells by factors in their microenvironment (niche). There are physical forces that provide regulation and education of cells necessary for deriving the components required for tissue construction, integration, and function. The possibilities for using ESC for tissue engineering are phenomenal, and the potential clinical applications are immense. However, there is much to learn about the cell and molecular biology of development and tissue regeneration, and we have only just begun to be informed.

### I. INTRODUCTION

Stem cell concepts have evolved dramatically over the last few years from the simple ideas in the literature in the mid-20th century. This has culminated in a rapid expansion of interest in both embryonic and adult tissue stem cells in the last five years with the development of interest in gene therapy, tissue engineering, and stem cell therapies. This chapter explores the evolution of stem cell concepts as applied to adult epithelial tissues. These tissues are characterized by a high degree of polarization and very distinct cell maturation and migration pathways, which permit the identification of specific locations in the tissues that represent the origins of all this cell movement. Cells at the origin of the migratory pathways must represent the cells on which the tissue is ultimately dependent and the cells that have a long-term (permanent) residence in the tissue, i.e., the stem cells. A variety of cell kinetic studies, together with lineage-tracking experiments, have indicated that in the intestine, the dorsal surface of the tongue, and interfollicular epidermis, the proliferative compartment of the tissue is divided into discrete units of proliferation. Each unit has its own stem cell compartment and adjacent family of stem cell progeny, including dividing transit cells and differentiated functional cells. In the skin the evolving stem cell studies suggest at least three distinct stem cell populations, providing a source of cells for the epidermis, for the growing hair follicle, and a reserve regenerative, highly potent population

in the upper follicle region. In the small intestine there are indications that the stem cell compartment itself is hierarchical, with a commitment to differentiation occurring two to three generations down the lineage, resulting in a population of actual stem cells that perform their function in steady state and a population of potential stem cells that can be called into action if the actual stem cells are killed. Until recently there have been no reliable markers for adult intestinal stem cells. However, recent developments have indicated ways in which these cells may be identified. Cancer is rare in the small intestinal epithelium, which is surprising, since this tissue represents a large mass, with many stem cells dividing many times. This suggests that effective genome protective mechanisms have evolved, and some aspects of these have now been identified.

In the 1950s and '60s, all proliferating cells in the renewing tissues of the body were regarded as having an equal potential to self-maintain, with one daughter cell (on average) from each division of a proliferative cell being retained within the proliferative compartment. Thus all proliferating cells were regarded as stem cells. It proved somewhat difficult to displace this concept. However, a groundbreaking paper by Till and McCulloch (1961) provided the first clear evidence for one of the replacing tissues of the body, the bone marrow, that not all proliferative cells are identical. The approach they employed was to study the cells that were capable of repopulating hemopoietic tissues,

following cellular depletion of the tissue by exposure to a cytotoxic agent, i.e., radiation. Specifically, mice were irradiated to deplete their bone marrow of endogenous, functional hematopoietic precursors; then they were injected with bone marrow–derived precursors obtained from another animal. The exogenous cells were subject to a variety of treatments prior to transplant, including irradiation. It was found that the hemopoietic precursors circulated in the host and seeded cells into various hemopoietic tissues, including the spleen. Those cells that seeded into the spleen and possessed extensive regenerative and differentiative potential grew by a process of clonal expansion to form macroscopically visible nodules of haemopoietic tissue 10–14 days after transplant. By appropriate genetic or chromosome tracking (marking), it could be shown that these nodules were derived from single cells, i.e., were clones, and that further clonogenic cells were produced within the clones. The colonies were referred to as *spleen colonies*, and the cells that formed the colonies were called *colony-forming units (spleen)* (CFU-s). These experiments provided the theoretical basis for subsequent human bone marrow transplant studies. By a variety of preirradiation manipulations and pre- and posttransplantation variables, this technique led to our current understanding of the bone marrow hierarchies, or cell lineages, and their stem cells. These studies showed that this tissue contained undifferentiated self-maintaining precursor cells that generated dependent lineages able to differentiate down a range of different pathways, generating a variety of cell types. Recent studies have suggested that these CFU-s are not the ultimate hemopoietic stem cells but are part of a stem cell hierarchy in the bone marrow.

Such clonal regeneration approaches have subsequently been developed for a variety of other tissues, notably by the imaginative approaches adopted by Rod Withers for epidermis, intestine, kidney, and testis. These clonal regeneration approaches were summarized and collected in a book produced in 1985 (Potten and Hendry, 1985), but readers are also specifically referred to Withers and Elkind (1970), which deals with the gut, and Withers (1967), for studies on the epidermis. These approaches implicated hierarchical organizations within the proliferative compartments of many tissues (Potten and Hendry, 1985). The stringency of the criteria defining a clone varied enormously, depending as it did on the number of cell divisions required to produce the detectable clones. For epidermis and intestine, the stringency was high, since the clones could be large and macroscopic, containing many cells resulting from many cell divisions, and in fact were very similar in appearance to the spleen colony nodules.

One difficulty with the interpretation of clonal regeneration studies and the generality of their application to stem cell populations is that in order to see the regenerating clones, the tissue has to be disturbed, generally by exposure to a dose of radiation, and this disturbance may alter the

cellular hierarchies that one wishes to study and will certainly alter the nature (e.g., cell cycle status, responsiveness to signals, susceptibility to subsequent treatment) of the stem cell compartment. This has been referred to as the biological equivalent of the Heisenberg uncertainty principle in quantum physics. However, these clonal regeneration assays do still provide a valuable and, in some places, unique opportunity to study some aspects of stem cell biology *in vivo*, i.e., by using this approach to look at stem cell survival and functional competence under a variety of conditions.

## II. A DEFINITION OF STEM CELLS

There have been relatively few attempts to define what is meant by the term *stem cells*, which has resulted in some confusion in the literature and the use of a variety of terms, the relationship between which sometimes remain obscure and confusing. These include *precursors*, *progenitors*, and *founder cells*. The concept is further complicated by the use of terms such as *committed precursors* and *progenitors* and the sometimes confusing use, or implication, of the term *differentiation*. One of the difficulties in defining stem cells is that the definitions are often very context dependent; hence, different criteria are brought into the definition by embryologists, haematologists, dermatologists, gastroenterologists, etc. In 1990, in a paper in *Development* (Potten and Loeffler, 1990), we attempted to define a stem cell. This definition was, admittedly, formulated within the context of the gastrointestinal epithelium, but we felt it had a broader application. The definition still largely holds and can be summarized as follows. Within adult replacing tissues of the body, the stem cells can be defined as a small subpopulation of the proliferating compartment, consisting of relatively undifferentiated proliferative cells that maintain their population size when they divide while at the same time producing progeny that enter a dividing transit population, within which further rounds of cell division occur together with differentiation events, resulting in the production of the various differentiated functional cells required of the tissue. The stem cells persist in the tissue throughout the animal's lifetime, dividing a large number of times, and, as a probable consequence of this large division potential, these cells are the most efficient repopulators of the tissue following injury. If this repopulation requires a reestablishment of the full stem cell compartment, the *self-maintenance probability* of the stem cells at division will be raised from the steady-state value of 0.5 to a value between 0.5 and 1, which enables the stem cell population to be reestablished while at the same time maintaining the production of differentiated cells to ensure the functional integrity of the tissue.

The consequences of this definition are obvious, namely that stem cells are:

- Rare cells in the tissue, vastly outnumbered by the dividing transit population, and are the cells on which the entire lineage and ultimately the tissue are dependent.

- The only permanent long-term residents of the tissue.
- Cells at the origin of any cell lineages or migratory pathways that can be identified in the tissue, producing progeny that differentiate.
- Cells that in steady state have a self-maintenance probability of .5, but this can be changed according to requirements.

The concept of *differentiation* enters into the definition of stem cells, and this also often leads to confusion. In our view, differentiation is a qualitative and relative phenomenon. Cells tend to be differentiated relative to other cells, hence, adult tissue stem cells may, or may not, be differentiated relative to embryonic stem cells (a point of current debate, bearing in mind the controversy in the literature concerning bone marrow stem cell *plasticity*). Stem cells produce progeny that may differentiate down a variety of pathways, leading to the concept of *totipotency* and *pluripotency* or *multipotency* of stem cells, in terms of their differentiation. This is actually a strange concept to apply to a stem cell since it is their progeny that differentiate and not the stem cells themselves. The fact is that the progeny can differentiate down more than one differentiated lineage, as is very obviously the case in the bone marrow, resulting in bone marrow stem cells being referred to as pluripotent; the initial dividing transit cells that initiate a lineage, which ultimately leads to specific differentiated cells, can be thought of as committed precursors for that lineage.

Some of the instructive signals for differentiation in the hemopoietic cell lineage are now well understood, but such signals for other tissues organized on a cell lineage basis have yet to be determined. There is much debate in the literature at present concerning the extent to which stem cells may be instructed to produce progeny of specific differentiated types and whether this is limited or unlimited. This topic is referred to as the *degree of plasticity* for stem cells. There are two very distinct issues here.

- The first is whether a stem cell, like a bone marrow stem cell, is ever instructed by its environment or niche naturally, or in laboratory or clinical situations, to make an apparently unrelated tissue cell type, such as a liver, intestinal, or skin cell, and whether it can regenerate these tissues if they are injured. A subsidiary question is not whether this ever happens normally in nature, but whether we, as experimentalists or clinicians, can provide the necessary instructions or environment for this to happen in a controlled situation.
- The second issue relates not only to the stem cells but also to the early progeny of stem cells from, for example, the bone marrow and whether these cells that circulate round the body and may end up in a distant tissue can end up expressing differentiation markers unrelated to the bone marrow cell lineages but specific to the tissue in which the cell then resides.

The former is an issue of plasticity of the bone marrow stem cells, and the latter may be more an issue of the plastic-

ity of the bone marrow-derived cell lineages. If a bone marrow stem cell can ever be instructed to be a gastrointestinal stem cell, it should be capable of undertaking all the functional duties of a gastrointestinal stem cell, including the regeneration of the gastrointestinal epithelium if it is subsequently injured. The cloning of animals by nuclear transfer technology into egg cytoplasm clearly demonstrates that all nuclei of the body contain a full complement of DNA and that, under the right environmental conditions, this can be reprogrammed (or unmasked) by environmental signals to make all the tissues of the body. It must be remembered that such cloning experiments, e.g., Dolly the sheep, are rare and inefficiently produced events. They do, however, clearly indicate the enormous potential that can be achieved if we provide the necessary instructive reprogramming signals. This should enable us in the future to reproducibly instruct any adult tissue stem cell to make any tissue of the body. If and when this becomes the case, the distinction between embryonic stem cells and adult tissue stem cells may disappear.

### III. HIERARCHICALLY ORGANIZED STEM CELL POPULATIONS

The issue here is what determines the difference between a dividing transit cell and a stem cell and whether that transition is an abrupt one or a gradual one. One can think of this transition as being a differentiation event that distinguishes a dividing transit cell from a stem cell. This is an old argument. Do differentiation signals act on preexisting stem cells, removing on average half the cells produced by previous symmetric divisions, or do the stem cells divide asymmetrically to produce a differentiated progeny at division and a stem cell? One possibility is that this distinction is made at the time that a stem cell divides. Indeed, does it need to divide to differentiate? In this case, such divisions must be regarded as asymmetric, with the dividing stem cell producing one stem cell (i.e., for self-maintenance) and one dividing transit cell. This type of asymmetric division may occur in some tissues, such as the epidermis. However, if this is the case, the stem cell must also retain the potential to alter its self-maintenance probability, which for an asymmetric division is 0.5 in steady state, and adopt a value somewhat higher than this if stem cells are killed and need to be repopulated. The current view regarding the bone marrow stem cells is that the transition between a stem cell and a dividing transit cell is a gradual one that occurs over a series of divisions within a cell lineage, which inevitably implies that one has a population of stem cells with a varying degree of stemness or, conversely, a varying degree of differentiation. For the bone marrow, one issue is whether experimentalists have ever identified the presence of the truly ancestral ultimate bone marrow stem cell. The difficulty here may be one of identifying and extracting such cells, the location of which is probably in the bone where

they will be present in increasingly diminishing numbers, as one looks for the increasingly primitive cells.

Our current model for the gastrointestinal cellular organization, which is based on an attempt to accommodate as much experimental data as possible, is that the commitment to differentiation producing dividing transit cells does not occur at the level of the ultimate stem cell in the lineage but at a position two or three generations along the cell lineage. If such a concept is drawn as a cell lineage diagram, the proliferative units in the intestine, the crypts, each contain four to six cell lineages and, hence, four to six lineage ancestor stem cells but up to 30 second- and third-tier stem cells, which under steady-state circumstances are inevitably displaced and moved toward the dividing transit compartment. But if damage occurs in one or more of the ultimate stem cells, they can assume the mantle of the ultimate stem cell and repopulate the lineage (Potten *et al.*, 1997; Potten, 1998; Marshman *et al.*, 2002). This gives rise to the concept of *actual vs. potential stem cells* (see Fig. 31.1), which is discussed later in this chapter.

An analogy can be drawn here with the hierarchical structure within an organization such as the army, a concept that was discussed at the time that we were formulating the text for the *Development* paper in which we defined stem cells (Potten and Loeffler, 1990). In a military battlefield environment, the hierarchically organized army is under the control of and ultimately dependent on the highly trained (or so one hopes) general. In the event that the general is killed in the battlefield, there may be a reasonably well-

trained colonel or major who can take over command and assume the insignia and uniform as well as the function of the general. In the event the colonel also should be killed, there may be lesser trained officers who will attempt to assume the mantle of command (e.g., a captain). Ultimately, the vast majority of the troops, the privates, would be insufficiently trained or experienced to be able to adopt the functional role of the commander. However, the Dolly the sheep scenario suggests that occasionally a private given a crash course in military strategy might function as the officer in command. The analogy could be taken even further to relate to the apoptosis sensitivity that is seen in the gastrointestinal ultimate stem cells. These cells appear to adopt a strategy with complete intolerance to any genetic damage and a reluctance to undertake repair, since this may be associated with inherent genetic risk they commit an altruistic suicide: the general who undergoes a nervous breakdown or suffers serious injury and has to be removed from command.

In the small intestinal crypts there have been in the past no useful markers that permit the stem cells to be identified and, hence, studied. However, such markers are now being identified. In the absence of markers, the small intestine proved to be an invaluable biological model system to study stem cells because the cells of the intestinal cell lineage are arranged spatially along the long axis of the crypt. This can be demonstrated by cell migration tracking and mutational marker studies. As a consequence, the stem cells are known to be located at very specific positions in the tissue (crypts):

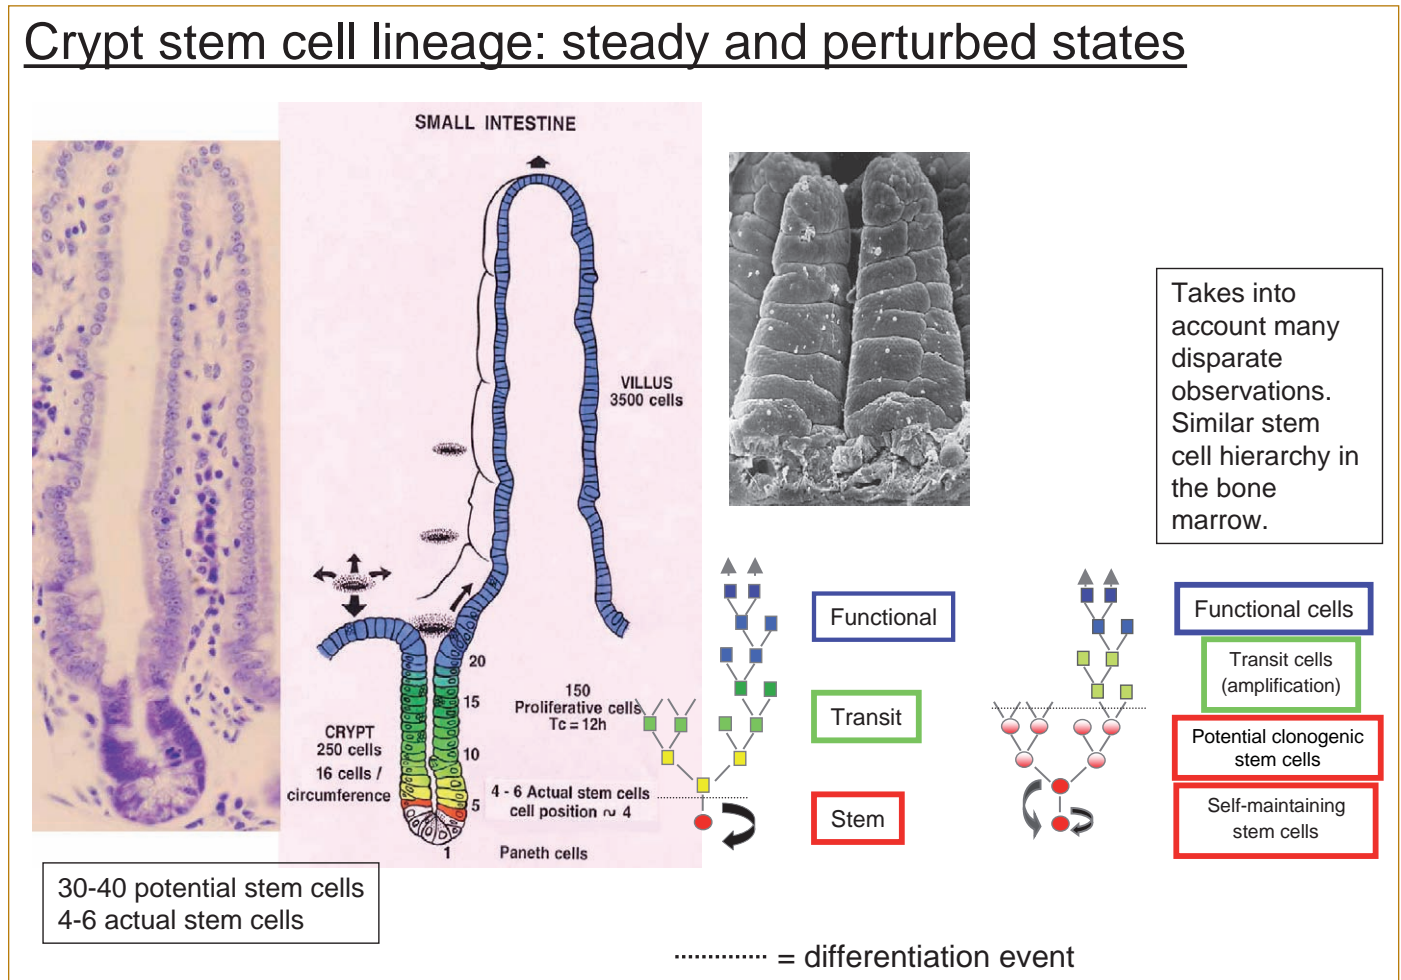

**FIG. 31.1.** A typical stem cell–derived cell lineage, which may be applicable to most epithelial tissues of the body. The lineage is characterized by a self-maintaining lineage ancestor actual stem cell (black), which divides and produces a progeny that enters a dividing transit population. The number of cell generations in the dividing transit population varies from tissue to tissue. The commitment to differentiation that separates the stem cell from the dividing transit population can occur at the point of the actual stem cell division (x), in which case the stem cells are dividing asymmetrically on average. However, this commitment may be delayed to point y or z, generating a population of potential stem cells that can replace the actual stem cell if it is killed. Under normal steady-state circumstances, the potential stem cells form part of the dividing transit population and are gradually displaced down the lineage, undergoing further differentiation events if required to produce the functional mature cells of the tissue.

the fourth to fifth cell position from the crypt base in the small intestine and at the very base of the crypt in the mid-colon of the large intestine (see Fig. 31.2) (Potten *et al.*, 1997; Potten, 1998; Marshman *et al.*, 2002).

#### IV. SKIN STEM CELLS

The first suggestion that the proliferative compartment of the epidermis, the basal layer, was heterogeneous and contained only a small subpopulation of stem cells came with the development of the skin macrocolony (and subsequently microcolony) clonal regeneration assays developed by Withers (Withers, 1967; Withers and Elkind, 1970). This was soon combined with other cell kinetic and tissue organization data to formulate the epidermal proliferative unit (EPU) concept (Potten, 1974) (see Fig. 31.3). This suggested that the basal layer consisted of a series of small, functionally and cell lineage-related cells, with a spatial organization that related directly to the superficial functional cells of the

epidermis, the stratum corneum. The concept indicated that the epidermis should be regarded as being made up of a series of functional proliferative units, each unit having a centrally placed self-maintaining stem cell and a short stem cell-derived cell lineage (with three generations). The differentiated cells, produced at the end of the lineage, migrated out of the basal layer into the suprabasal layers in an ordered fashion, where further maturation events occurred, eventually producing the thin, flattened, cornified cells at the skin surface, which were stacked into columns (like a pile of plates), with cell loss occurring at a constant rate from the surface of the column (Fig. 31.3). Such an organization is clearly evident in the body skin epidermis of the mouse, its ears, and a modified version of the proliferative unit can clearly be identified in the dorsal surface of the tongue (Hume and Potten, 1976). There has been, and continues to be, some debate as to whether this concept applies to human epidermis. It is clear that in many sites of the body in man

**FIG. 31.2.** The cell lineage for the small intestinal crypts. It is postulated that each crypt contains four to six such lineages and, hence, four to six lineage ancestor actual stem cells, and there are about six cell generations in each lineage with at least four distinct differentiated cell types being produced. The attractive feature of this as a cell biological model system is that the position of a cell in a lineage can be related to its topographical position in a longitudinal section through the crypt.

## Stem cells in the epidermis

**FIG. 31.3.** Diagrammatic representation of the cell lineage seen in the interfollicular epidermis and the relationship between the cell lineage and the spatial organization, characterized as the epidermal proliferative unit (EPU), as seen in section view (upper portion of the figure on the left) and in surface view in epidermal sheets (lower portion of the figure on the left). The old historical lineage model is shown on the left and an alternative model to the current one on the right.

a similar columnar organization can be seen in the superficial corneal layers of the epidermis. What is more difficult in humans is to relate this superficial structure to a spatial organization in the basal layer. However, the spatial organization seen in the superficial layers must have an organizing system at a level lower in the epidermis, and it does not seem unreasonable to assume that this is in the basal layer, as is the case of the mouse epidermis. The presence of units of proliferation in human epidermis has been demonstrated using  $\beta$ -galactosidase/GFP staining of skin in cultures and xenografts (MacKenzie, 1997; Ghazizadeh and Taichman, 2005).

A macroscopic, clonal regeneration assay for mouse epidermis was developed by Withers (1967), which generates nodules very similar in appearance to spleen colonies. Subsequently, Al-Barwari developed a microscopic clonal assay that required a shorter time interval between irradiation and tissue sampling (Al-Barwari and Potten, 1976). Together, these clonal regeneration assays were interpreted

to indicate that only about 10% (or less) of the basal cells have a regenerative capacity, i.e., are stem cells.

The EPU stem cells must have an asymmetrical division mode under steady-state cell kinetics, since there is only one such cell per EPU. The epidermal microcolony assay developed by Al-Barwari suggests that, following injury such as irradiation, surviving EPU stem cells can change their division mode from asymmetric to symmetric for a period of time to repopulate the epidermis (i.e., change their self-maintenance probability from 0.5 to a value higher than 0.5). Al-Barwari's observations also indicated that a significant contribution to reepithelialization could come from the upper regions of the hair follicles. This has subsequently been expanded into a major area of interest: The hair follicle lineage stem cells have been shown to possess a wide range of regenerative activities, including production of epidermis. It was also clear from studies on the structural organization of the epidermis following injury that in order to reestablish the spatial distribution of stem cells, the epider-

mis undergoes a reorganization involving hyperplasia, during which stem cells are redistributed and eventually establish their EPU spatial configurations.

The skin clearly contains another important stem cell population, namely that associated with the growing hair follicles. Hair is produced over a protracted period of time by rapid divisions in the germinal region of the growing hair follicle (termed an *anagen follicle*). This hair growth may be maintained for long periods of time, three weeks in a mouse (where the average cell cycle time may be 12 h), months to years in man, and for more indefinite periods for some animal species, such as Angora rabbits, merino sheep, and some strains of dog. This high level of cell division in the germinal matrix of the follicle, which has a considerable spatial polarity like the intestinal crypt, must have a fixed stem cell population residing in the lowest regions of the germinal matrix that can maintain the cell production for the required period of time. Very little is known about these stem cells. The complication with hair follicles is that in mouse and man, the growing follicles eventually contain a mature hair and cell proliferation activity ceases. The follicle shrinks and becomes quiescent (a *telogen follicle*). The simplest explanation here is that the telogen follicle, which consists of far fewer cells in total than in a growing follicle, contains a few quiescent hair follicle stem cells that can be triggered back into proliferation at the onset of a new hair growth cycle. However, as discussed later, there is some controversy concerning this concept.

It is now very clear that the skin contains a third stem cell compartment, which is located in the upper outer sheath of the hair follicle, below the sebaceous glands. This is sometimes identifiable by virtue of a small bulge in the outer root sheath, and so this population of cells has been referred to as the *bulge* cells. What is very evident from a whole series of extremely elegant but complicated experiments is that these bulge cells possess the ability, under specialized conditions, to reform the hair follicle if it is damaged and also to contribute to the reepithelialization of the epidermis. It is cells from this region of the follicle that were probably responsible for the epidermal reepithelialization from follicles seen by Al-Barwari. Cells from the bulge can make follicles during development of the skin and also reestablish the follicles if they are injured. The controversy concerns the issue of whether bulge stem cells, which are predominantly quiescent cells, ever contribute to the reestablishment of an anagen follicle under normal undamaged situations. The simplest interpretation is that these cells are not required for this process, since in order for this to happen some very complex cell division and cell migratory and homing pathways have to be inferred. This goes somewhat against the concept of stem cells being fixed or anchored and also against the concept of keratinizing epithelia being a tightly bound strong and impervious barrier. What seems likely for the skin is that the EPU stem cell and the hair follicle stem cell have a common origin

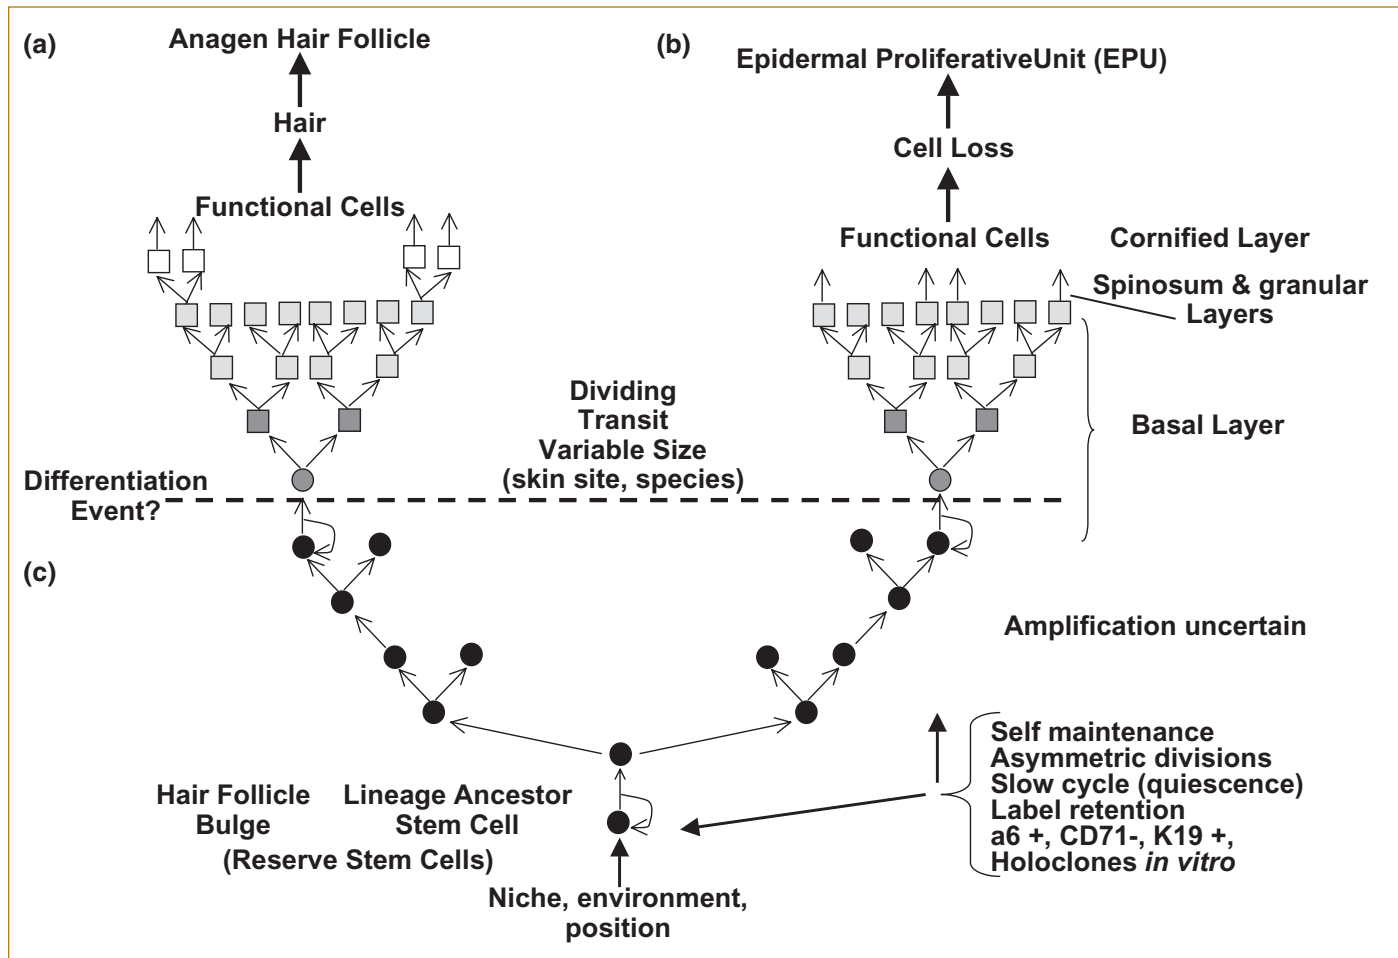

during the development of the skin to the bulge stem cells, which then become quiescent and are present as a versatile “reserve” stem cell population that can be called into action if the skin is injured and requires reepithelialization (see Figs. 31.4 and 31.5) (Potten and Booth, 2002).

Another issue relating to the stem cells of the bulge region of the follicle is that they are defined, usually by immunohistochemistry, as being present as a “cluster” of largely quiescent cells. If these “reserve” cells are called into action, which cells divide? If the cells toward the center of the cluster divide, this will inevitably push the peripheral cells out of the cluster — so they were not stem cells in the first place. If the cells at the periphery divide, there is no need for the cells toward the center — so they do not satisfy stem cell criteria. The most likely explanation is that the cluster contains only a few (one or two?) *real* stem cells at the center and that the rest are quiescent early lineage cells.

Quiescence is a property often stated as applicable to stem cells. It is certainly true that in many, but not all, replacing tissues the stem cells are cycling more slowly than the transit cells (longer G1 phase). The *Oxford English Dictionary* defines *quiescence* as “a state of motionless, inertness, silence, dormancy, or inactivity.” Stem cells are usually defined by virtue of what they can do. If they are doing nothing, can they be stem cells?

## V. INTESTINAL STEM CELL SYSTEM

The intestinal epithelium, like all epithelia, is highly polarized and divided into discrete units of proliferation and differentiation. In the small intestine the differentiated units are the fingerlike villi protruding into the lumen of the intestine. These structures are covered by a simple columnar epithelium consisting of several thousand cells, which perform their specific function, become worn out, and are shed, predominantly from the tip of the villus. There is no proliferation anywhere on the villus. The cell loss from the villus tip is precisely balanced in steady state by cell proliferation at the base of the villi in units of proliferation called *crypts*. Each villus is served by about six crypts, and each crypt can produce cells that migrate onto more than one villus. The crypts in the mouse contain about 250 cells in total, 150 of which are proliferating rapidly and have an average cell cycle time of 12 hours. The cells move from the mouth of the crypt at a velocity of about one cell diameter per hour, and all this movement can be traced, in the small intestine, back to a cell position about four cell diameters from the base of the crypt. The very base of the crypt, in mice and humans, is occupied by a small population of functional differentiated cells called *Paneth* cells. Cell migration tracking and innumerable cell kinetic experiments all suggest that the stem cells that represent the origin of all this cell movement are located at the fourth position from the base of the crypt in the small intestine and right at the base of the crypt in some regions of the large bowel. The crypt is

**FIG. 31.4.** The complexity of the stem cell populations in mammalian skin as characterized in the mouse. (a) A distinct cell lineage is proposed for the interfollicular epidermis (EPU), (b) another is proposed for the matrix region of the growing hair follicle (anagen follicle), and (c) a potent reserve regenerative stem cell compartment, which resides in the upper/outer root sheath or bulge region of the hair follicle, is proposed. The stem cells in the bulge region can clearly regenerate the epidermis, the hair follicle, and probably other structures, such as the sebaceous glands.

a flask-shaped structure, about 16 cells in circumference. Mathematical modeling suggests that each crypt contains about five cell lineages and, hence, five cell lineage ancestor stem cells. Under steady-state kinetics these cells are responsible for all the cell production, producing daughters that enter a dividing transit lineage of between six and eight generations in the small and large bowel, respectively (see Figs. 31.1 and 31.2). The stem cells in the small intestine divide with a cycle time of approximately 24 hours; hence, in the lifetime of a laboratory mouse they divide about 1000 times. It is assumed that these cells are anchored or fixed in a micro-environmental niche that helps determine their function and behavior. The uniquely attractive feature of this model system, from a cell biological point of view, is that in the absence of stem cell-specific markers, the behavior and characteristics and response to treatment of these crucial lineage ancestor cells can be assessed by studying the behavior of cells at the fourth position from the bottom of the crypt in the small intestine. When this is done, one of

the features that seems to characterize a small population of cells at this position (about five cells) is that they express an exquisite sensitivity to genotoxic damage, such as delivered by small doses of radiation (Potten, 1977; Hendry *et al.*, 1982; Potten and Grant, 1998). They appear to tolerate no DNA damage and activate a p53-dependent altruistic suicide (apoptosis). It is believed that this is part of the genome protection mechanisms that operate in the small intestine and account for the very low incidence of cancer in this large mass of rapidly proliferating tissue.

The clonal regeneration techniques for the intestine developed by Withers (Withers and Elkind, 1970) have been used extensively. These techniques suggest the presence of a second compartment of clonogenic or potential stem cells (about 30 per crypt) that possess a higher radioresistance and a good ability to repair DNA damage. These observations, together with others, suggest a stem cell hierarchy of the sort illustrated in Figs. 31.1 and 31.2, with the commitment to differentiation that distinguishes dividing transit

**FIG. 31.5.** Diagrammatic representation of a growing anagen hair follicle and a resting or quiescent telogen follicle. Photomicrographs of representative anagen and telogen follicles are inset.

cells from stem cells, occurring about three generations along the lineage. Virtually identical lineage structures can be inferred for the colonic crypts (Cai *et al.*, 1997).

There has been an absence of stem cell-specific markers in the past. However, current work suggests that some may now be available. Antibodies to Musashi-1, an RNA-binding protein identified as playing a role in asymmetric division control in neural stem cells, appears to be expressed in very early lineage cells in the small intestine (see Fig. 31.6) (Potten *et al.*, 2003).

Recent studies have indicated that the ultimate stem cells in the crypt possess the ability selectively to segregate old and new strands of DNA at division and to retain the old template strands in the daughter cell destined to remain a stem cell while passing the newly synthesized strands, which may contain any replication-induced errors, to the daughter cell destined to enter the dividing transit population and to be shed from the tip of the villus five to seven days after birth from division (Potten *et al.*, 2002). This selective DNA segregation process provides a second level of genome protection for the stem cells in the small intestine (Cairns, 1975), protecting them totally from the risk of replication-induced errors, thus providing further protection against carcinogenic risk and an explanation for the very low cancer incidence in this tissue (see Table 31.1). This mechanism of selective DNA segregation allows the template strands to be labeled with DNA synthesis markers at times of stem cell expansion, i.e., during late tissue development and during tissue regeneration after injury. The incorporation of label into the template strands persists (label-retaining cells),

**Table 31.1.**

Why do small intestinal stem cells not develop more cancers?

When one considers that:

- the tissue is 3–4 times greater in mass (length)
- the cells are proliferating 1.5 times more rapidly
- there are 2–3 times more total stem cells
- there are 3–4 times more stem cell divisions in a lifetime

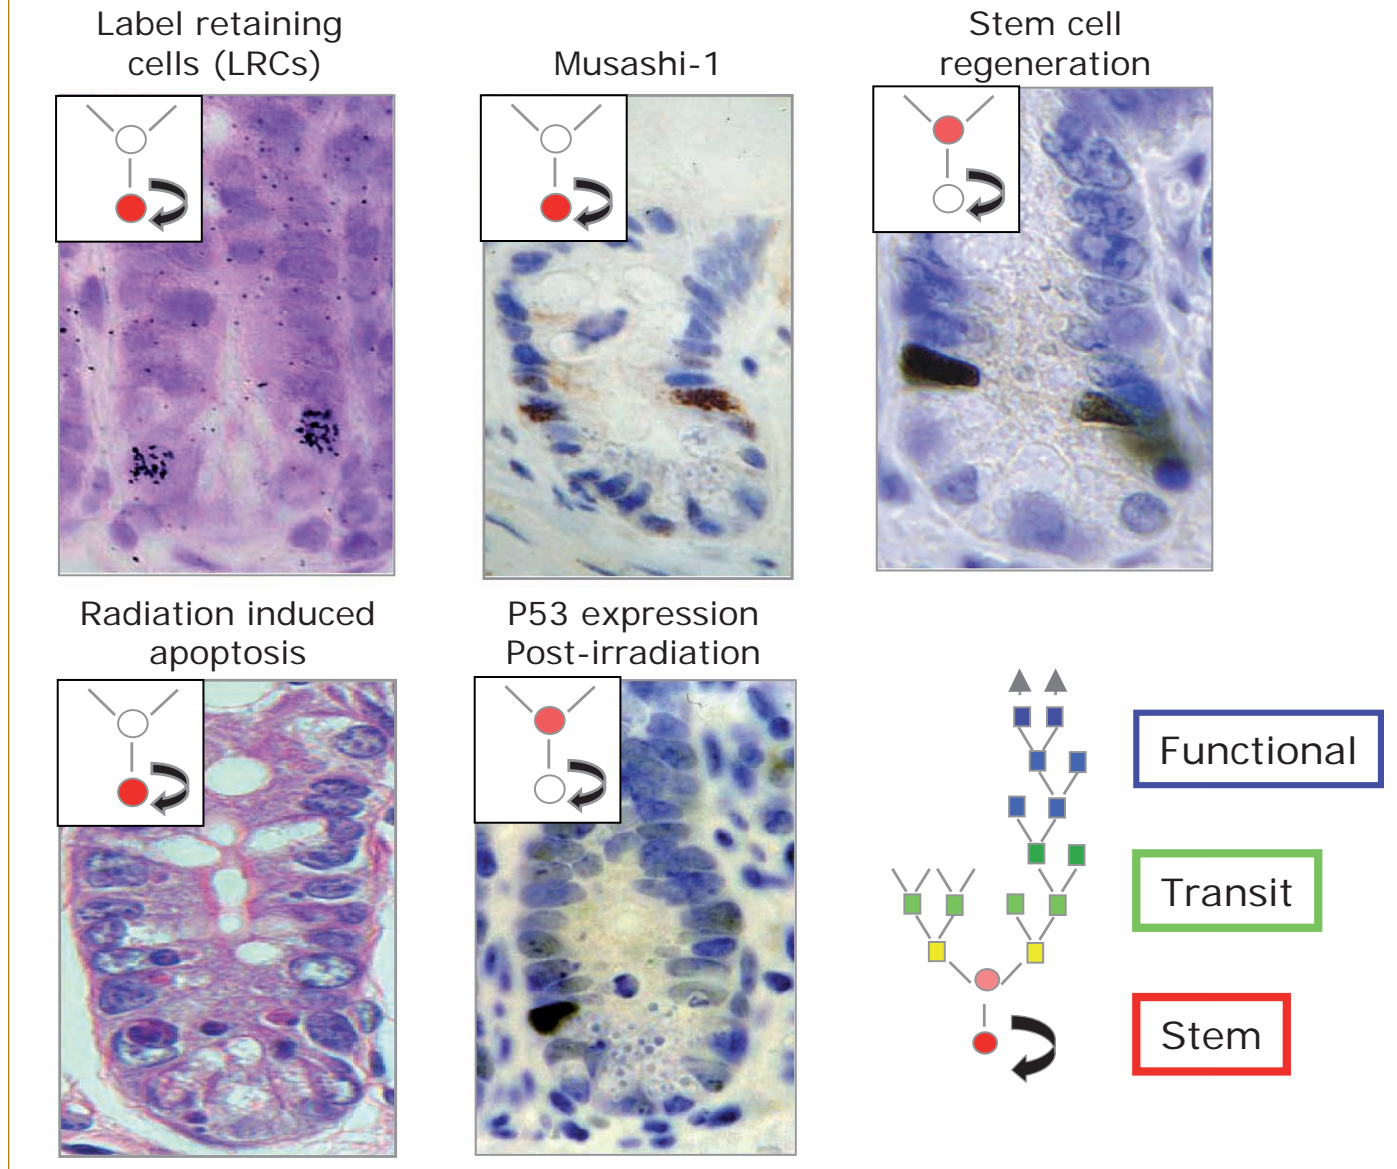

Compared with the large intestine, the small intestine has 70 times fewer cancers.

thus providing a truly specific marker for the lineage ancestor cells (see Fig. 31.6). This figure also illustrates some other ways in which intestinal stem cells may be distinguished from their rapidly dividing progeny.

The selective segregation of “old” and “new” DNA strands at mitosis is appearing to be a universal feature of the rare ultimate adult tissue stem cell. In addition to the small intestinal epithelium, this process has been detected in breast epithelial stem cells, both *in vivo* and *in vitro*, in neural stem cells *in vitro*, and in some muscle satellite cells (Merok *et al.*, 2002; Clarke *et al.*, 2005; Karpowicz *et al.*, 2005; Pare and Shirley *et al.*, 2006; Shinin *et al.*, 2006). It can also be inferred from work on the dorsal surface of the tongue and epidermis.

## Stem cell identification / responses

**FIG. 31.6.** Photomicrographs of longitudinal sections of the small intestinal crypts from the mouse, illustrating a range of possible ways of identifying the stem cell compartment. Making use of the selective strand segregation hypothesis, template strands of DNA can be labeled, generating label-retaining cells at the fourth position from the bottom of crypts. Musashi-1, an RNA-binding protein, is expressed in early lineage cells and under some labeling conditions can show specificity for individual cells at around cell position 4. Part of the regenerative or potential stem cell compartment can be seen by S-phase labeling (Bromodeoxyuridine labeling) at critical phases following cytotoxic injury, when these cells are called into regenerative mode. The example shown here is a labeling pattern at 24 hours after two doses of 5-fluorouracil, when the only cells in S phase are a few cells scattered around the fourth position from the base of the crypt. As part of the genome protective mechanism it is postulated that the ultimate lineage ancestor stem cells have an exquisite sensitivity to radiation and the induction of genome damage. When this happens, the cells commit suicide via apoptosis, which can easily be recognized and occurs at about the fourth position from the base of the crypt. These cells do not express p53 protein, at least at the times studied and as detectable by immunohistochemistry. However, some cells do express p53 protein at high levels following radiation exposure, and it is postulated that these are the surviving potential stem cells in cell cycle arrest, to allow for repair prior to entering rapid regenerative cell cycles. Under appropriate immunohistochemical preparative procedures, individual wild-type P53 protein-expressing cells can be seen at around cell position 4. The cartoons represent the cell within the lineage, which is thought to be labeled by each marker (stem cell = red; stem cell daughter/early progenitor = pink).

## VI. STEM CELL ORGANIZATION IN FILIFORM PAPILLAE ON THE DORSAL SURFACE OF THE TONGUE

Oral mucosae are keratinizing, stratified epithelia, similar to epidermis in their structural organization. The dorsal surface of the tongue is composed of many small, filiform papillae that have a very uniform shape and size. Detailed histological investigations, together with cell kinetic studies performed by Hume (Hume and Potten, 1976), showed that each papilla is composed of four columns of cells: two dominant and two buttressing columns. The dominant anterior and posterior columns represent modified versions of the epidermal proliferative units and were called *tongue proliferative units*. The cell migratory pathways were mapped (like the studies in the intestinal crypts), which enabled the position in the tissue from which all migration originated to be identified, this being the presumed location of the stem cell compartment. The lineage characterizing this epithelium is similar to that seen in the dorsal epidermis of the mouse, i.e., self-replacing asymmetrically dividing stem cells, occurring at a specific position in the tissue, producing a cell lineage that has approximately three generations (Fig. 31.7). The stem cells

here have a particularly pronounced circadian rhythm (Potten *et al.*, 1977a).

## VII. GENERALIZED SCHEME

It thus appears that for the major replacing tissues of the body, hierarchical or cell lineage schemes appear to explain the cell replacement processes. These schemes may involve isolated single stem cells that, under steady-state circumstances, must be presumed to divide asymmetrically, producing a dividing transit population. The size of the dividing transit population differs dramatically from tissue to tissue. The number of generations defining the degree of amplification that the transit population provides for each stem cell division is related inversely to the frequency that stem cells will be found within the proliferating compartment (see Fig. 31.8). For some systems, such as the bone marrow and the intestine, the commitment to differentiation that separates the dividing transit compartment from the stem cell compartment appears to be delayed until a few generations along the lineage. This generates a stem cell hierarchy, with cells of changing (decreasing) stemness or, conversely, increasing commitment, leading to the concept of committed precursor cells. In the small intestine this delay in the commitment to differentiation to a dividing transit

### Tongue proliferative units (TPUs) - Filiform papillae

**FIG. 31.7.** A scanning electron micrograph of (left) and histological section through the dorsal surface of the tongue (center), and a diagrammatic representation of this tissue (right), showing the tongue proliferative units (the dominant anterior column, AC, and posterior column, PC). Cell migratory pathways have been identified based on cell positional analyses and cell marking and on the location of the stem cells identified in the basal layer (red diamond — cell position 1). The stem cells in this tissue express one of the strongest circadian rhythms in proliferation seen anywhere in the body.

**FIG. 31.8.** A diagrammatic representation of a stem cell–derived cell lineage, showing the approximate positions for the number of cell generations in the dividing transit population for a range of murine tissues. Stratified keratinizing epithelia, such as the breast, tongue, and epidermis, tend to have the shortest lineages; the bone marrow and the testis tend to have the longest lineages. Also shown is the degree of theoretical amplification that the dividing transit lineage provides for each stem cell division and the inverse relationship between the degree of amplification and the proportion of the proliferative compartment that the stem cells occupy.

population provides the tissue with a reserve population of potential stem cells that can repopulate the tissue if the lineage ancestor cells are destroyed, an added level of tissue protection in this extremely well-protected tissue. With regard to the bone marrow, committed precursors (or even earlier cells) appear to circulate in the blood and may lodge in various tissues. Given appropriate microenvironments and local signals, some of these lodged cells may be instructed to differentiate down unusual pathways. This has prompted research into using such cells to correct genetic deficiencies. Although the transdifferentiation theory is attractive, recent research indicates that the apparent plasticity of stem cells may be less clear-cut. Transplantation experiments in mice with specific gene disorders suggest that transplanted bone marrow cells may “fuse” with cells in the “target” organ and, hence, complement any gene deficiency.

## VIII. ADULT STEM CELL PLASTICITY

Recently, a number of significant papers on the plasticity of bone marrow progenitor cells have been published that focus on their ability to contribute to the different pro-

liferative cell compartments of the intestinal epithelium (and other cell types of the intestinal mucosa). In an elegant series of experiments, bone marrow progenitor cells from a male donor were injected into female recipient mice, which were subsequently subject to induction of mucosal injury (Brittan *et al.*, 2005). Alternatively, bone marrow progenitors were injected into lethally irradiated female mice (Brittan *et al.*, 2002; Brittan and Wright, 2004). *In situ* hybridization was able to demonstrate cells with a male Y chromosome within the regenerating endothelium and within the pericryptal fibroblast cell population (the cells that surround the crypt epithelial cells on the basolateral side), but not within the colonic epithelium. The fibroblasts with male chromosomes appeared as columns of cells along the crypt axis within the tissue sections examined, suggesting that bone marrow–derived cells had established a clonal lineage within the proliferative fibroblast cell population.

Other studies have suggested that bone marrow progenitors can contribute to all the different cell lineages within the intestinal epithelium (Rizvi *et al.*, 2006). In mice, injection of labeled female bone marrow progenitor cells

into lethally irradiated male mice resulted in cells with female-specific label being found within the proliferative cells of the small intestinal crypts and within the various differentiated cell populations of the villi (columnar, goblet, enteroendocrine, Paneth). The conclusion was that female bone marrow progenitors “fused” with stem or early progenitor cells of the intestinal epithelium of the male recipient. Fusion rather than transdifferentiation was suggested as a mechanism in this study, based on the high frequency of cells that were positive for the female-specific marker and the male Y chromosome. In humans, cells from male donors have been found throughout the gastrointestinal tract epithelium of female recipients (Okamoto *et al.*, 2002). It was suggested that the donor cells were able to incorporate into the epithelium and differentiate into mature epithelial cells but did not integrate into the stem cell compartment.

In addition to the regenerating epithelium postinjury, high levels of intestinal epithelial cell proliferation are to be found within tumors of epithelial origin. Further experiments examining the incorporation of female bone marrow progenitors into intestinal tumors of male *Min/+* mice revealed a large number of epithelial cells within the tumors, which were double positive for male- and female-specific markers (Rizvi *et al.*, 2006). These results paralleled those from the lethal-irradiation experiments and suggest that cell fusion between bone marrow progenitors and epithelial cells is common (within the intestinal epithelium at least) in situations when cell proliferation rates are elevated. It also raises the possibility that bone marrow progenitors can contribute to tumor progression.

This last point is rather controversial, and, to date, only one study has suggested that bone marrow progenitors are

directly responsible for tumor development within an epithelial tissue (Houghton *et al.*, 2004). Mice had their bone marrow ablated by irradiation and received a bone marrow transplant from ROSA26 transgenic mice. They were then infected with *Helicobacter felis*, in order to induce gastric carcinogenesis. The mice showed classic progression from metaplasia to dysplasia to carcinoma, over the period of one year, with most dysplastic gastric glands and all neoplasia being derived from the bone marrow progenitors, as assessed by their expression of the ROSA26 transgene. Experiments examining male donor/female recipient combinations failed to show colocalization of male- and female-specific markers in isolated gastric epithelial cells, which suggests that stable fusion events between the bone marrow progenitor cells and gastric epithelial cells do not take place in this experimental system. As evidence for transdifferentiation of bone marrow cells, the authors were able to present evidence of epithelial cell-specific gene expression in bone marrow-derived mesenchymal stem cell cultures exposed to conditioned medium from gastric epithelial cell primary cultures.

It can be clearly seen that different experimental models offer different perspectives on the relative merits of stem cell transdifferentiation and fusion and their ability to contribute to different cell populations within epithelial tissues. There is the possibility that in a highly proliferative tissue like the gastrointestinal epithelium, bone marrow transplantation may introduce into the tissue a population of cells that are a “low-threshold” target for induction of tumorigenesis; however, this still requires further evidence to show whether this is a real phenomenon or just a peculiarity of the experimental model. This aside, adult stem cell transplantation clearly has exciting potential for promoting tissue regeneration following injury.

### I. INTRODUCTION

Tissue engineering may one day generate off-the-shelf organs for transplantation that may be able to treat a variety of debilitating ailments, such as diabetes and Parkinson's disease. One of the major barriers to realization of this enormous potential is the lack of a renewable source of cells for transplantation. Embryonic stem cells (ESCs) have the potential to provide such a source of cells because of their ability to differentiate to all somatic cells and their seemingly unlimited proliferative capability. In this chapter we address the potential and the challenges associated with the use of ESC in tissue engineering. In particular we address methods to proliferate and direct ESC differentiation, to isolate and transplant ESCs, and to incorporate these cells into existing tissue-engineering approaches. In addition, we address issues associated with the host's immune rejection, ESC-derived tumor formation, and scale-up processes.

It has been estimated that approximately 3000 people die every day in the United States from diseases that could have been treated with stem cell-derived tissues (Lanza *et al.*, 2001). Given the therapeutic potential and growing public awareness of stem cells to treat disease, it is not surprising that embryonic stem cell (ESC) research has been rapidly expanding since mouse ESC (mESC) were first

isolated in 1981 (Evans and Kaufman, 1981; Martin, 1981) followed by the isolation of human embryonic stem cells (hESCs) in 1998 (Shamblott *et al.*, 1998; Thomson *et al.*, 1998) from the inner cell mass (ICM) of human blastocysts (Fig. 32.1). Adult stem cells have been used clinically for therapies such as bone marrow transplantation since the 1960s. Although adult stem cells hold great therapeutic promise, ESCs represent an alternative source of cells, with benefits including ease of isolation, ability to propagate rapidly without differentiation, and potential to form all cell types in the body. Additionally, ESCs represent an attractive cell source for the study of developmental biology, for drug/toxin screening studies, and for the development of therapeutic agents to aid in tissue or organ replacement therapies. Regarding the latter, which is the focus of this chapter, ESCs have the potential to exhibit a considerable impact on the field of tissue engineering, where current treatments for large tissue defects involve graft procedures having severe limitations. Specifically, many patients with end-stage organ disease are unable to yield sufficient cells for expansion and transplantation. In addition, there exists an inadequate supply of harvestable tissues, for grafting has associated risks, such as donor site morbidity, infection, disease transmission, and immune rejection. Tissue engineering-based

**FIG. 32.1.** Schematic diagram of the derivation of embryonic stem cells.

therapies may provide a possible solution to alleviate the current shortage of organs.

Tissue engineering has been defined as an interdisciplinary field that applies the principles of engineering, materials science, and life sciences toward the development of biologic substitutes that restore, maintain, or improve tissue function (Langer and Vacanti, 1993). Thus, tissue engineering may provide therapeutic alternatives for organ or tissue defects that are acquired congenitally or by cancer, trauma, infection, or inflammation. Tissue-engineered products would provide a life-long therapy and may greatly reduce the hospitalization and health care costs associated with drug therapy while simultaneously enhancing the patients' quality of life.

A central part of such promising strategies is the cell source to be used and the methods whereby sufficient numbers of viable differentiated cells can be obtained. ESCs represent a powerful source of cells capable of multilineage differentiation because they can potentially provide a renewable source of cells for transplantation. ES-derived cells can be used directly as cellular replacement parts or in combination with materials (typically in the form of scaffolds, Fig. 32.2). Despite this promise, the application of ESC to tissue engineering faces numerous challenges, including appropriately differentiating the cells to the desired lineage in a controlled and homogenous fashion and avoiding implantation of undifferentiated ESCs, which can potentially form teratocarcinomas. Currently, ESC-based tissue-engineering research is focused on elucidating soluble and immobilized cues and respective signaling mechanisms that direct cell fate, on characterization and isolation of differentiated progeny, and on establishing protocols to improve the expansion and homogeneity of differentiated cells.

This chapter discusses key concepts and approaches for (1) propagation of undifferentiated ESCs, (2) directed differentiation into tissue-specific cells, (3) isolation of pro-

**FIG. 32.2.** Approaches for using ES cells for scaffold-based tissue-engineering applications. ES cells can be used in tissue-engineering constructs in a variety of methods. ES cells can be expanded in culture and then seeded directly onto scaffold, where they are allowed to differentiate. Alternatively, stem cells can be directed to differentiate into various tissues and enriched for desired cells prior to seeding the cells onto scaffolds.

genitor and differentiated phenotypes, (4) transplantation of progenitor and differentiated cells, and (5) remaining challenges for translating ESC-based tissue-engineering research into clinical therapies. Whenever possible, approaches using hESCs will be preferentially reported.

## II. MAINTENANCE OF ESCS

The self-renewal of ESCs is a prerequisite for generating a therapeutically viable amount of cells. Over the past few years, much insight has been gained into self-renewal of ESCs. Both mouse and human ESCs were first derived and routinely maintained in culture at an undifferentiated state on mouse embryonic fibroblast feeder (MEF) layers with medium containing serum. Through this research considerable behavioral, morphological, and biochemical differ-

ences have been observed between mESCs and hESC, and research on nonhuman embryonic cells is often not easily translated to humans (Ginis *et al.*, 2004; Park *et al.*, 2004; Thomson *et al.*, 1998). For example, mESCs form tight, rounded clumps, whereas hESCs form flatter, looser colonies, grow more slowly, and demand strict culture conditions to maintain their normal morphology and genetic integrity. Unlike mESC, which can be maintained in an undifferentiated state in the presence of leukemia-inhibitory factor (LIF), LIF alone is not sufficient to maintain hESC cultures, which require supplementation with basic fibroblast growth factor (bFGF) or the presence of a feeder layer. Although both mouse and human ESC express common transcription factors of stemness, such as Nanog, Oct4, and alkaline phosphatase, in the human system undifferentiated ESC express stage-specific embryonic antigen-3 (SSEA-3) and SSEA-4, while SSEA-1 is expressed only on differentiation; the opposite expression is observed in the mouse system. Due to these differences, efforts in hESC research focus on improving culture conditions to allow better expansion in undifferentiated state as well as on understanding the mechanisms of hESC self-renewal.

Since the primary therapeutic aim of the research on hESCs is to derive cells for the replacement of diseased or damaged tissues, difficulties concerning xenograft transplantation had arisen. Moreover, all potential applications depend largely on the routine availability of moderate to large numbers of cells requiring methods amenable to scale-up. Addressing the xenograft obstacle, Richards *et al.* examined the culture of hESCs cells on human feeders and found that human fetal muscle fibroblasts, human fetal skin fibroblasts, and adult fallopian tubal epithelial cells supported the pluripotency of hESCs culture *in vitro* (Richards *et al.*, 2002). Richards *et al.* further derived and established an hESC line on human fetal muscle fibroblasts in entirely animal-free conditions. Since then, different fetal and adult cells were examined and shown to support the continuous growth of hESC (Amit *et al.*, 2003; Cheng *et al.*, 2003; Hovatta *et al.*, 2003; Richards *et al.*, 2003). However, the use of hESCs for therapeutic applications requires defined culture medium and controlled cell derivation, maintenance, and scale-up. To overcome these obstacles, C. Xu *et al.* (2001) showed that hESCs can be maintained on Matrigel or laminin in MEF-conditioned medium. Cells grown in these conditions meet all the criteria for pluripotent cells: They maintain normal karyotypes, exhibit a stable proliferation rate and high telomerase activity, and differentiate into derivatives of all three germ layers, both *in vitro* and *in vivo*. Recent studies further defined culture conditions and show that hESCs can be expanded on human fibronectin using medium supplemented with bFGF and tumor growth factor  $\beta$ 1 (TGF $\beta$ 1) (Amit *et al.*, 2004). Noggin, an antagonist of bone morphogenetic protein (BMP), was found critical in preventing differentiation of hESC in culture. The combina-

tion of Noggin and bFGF is sufficient to maintain the proliferation of undifferentiated hESCs (R. H. Xu *et al.*, 2005). Furthermore, hESCs maintained in medium containing high concentrations of bFGF (24–36 ng/mL), alone or in combination with other factors, show characteristics similar to cultures maintained with feeder cell-conditioned medium (Wang *et al.*, 2005; C. Xu *et al.*, 2005). The derivation of hESCs has also been achieved with minimal exposure to animal-derived material, using serum replacement (SR) and human foreskin fibroblasts as feeder cells (Inzunza *et al.*, 2005), instead of the murine feeder layer (Klimanskaya *et al.*, 2005), which may provide well-defined culture conditions (Ludwig *et al.*, 2006). Research is currently under way to determine how these conditions maintain cell integrity over long-term culture.

Although laboratory-scale ESC cultures have been shown to produce differentiated progeny for both rodent and human ESCs, it is generally acceptable that these culturing methods are not feasible for large-scale production of ESCs for therapeutic applications. Although two-dimensional methods, such as the high-density cultures of undifferentiated mESCs, have been developed by combining automated feeding and culture of mESCs on petriperm dishes (Oh *et al.*, 2005), the three-dimensional culture of ESC may be a more suitable technology for large-scale expansion of ESCs.

At the present time, the aggregation of multiple ESCs is an obligatory process to initiate EB formation. A few methods have been developed for the differentiation of mESC in controlled cultures. Hanging drops and methylcellulose cultures were shown to be somewhat efficient in preventing the agglomeration of EBs, but their complex nature makes their up-scaling a rather difficult task. A much simpler process, however, involving spinner flasks, resulted in the formation of large cell clumps within a few days, indicative of significant cell aggregation in the cultures (Wartenberg *et al.*, 2001). An increase of the culture medium's stirring rate, to avoid agglomeration, resulted in massive hydrodynamic damage to the cells, due to the extensive mixing in the vessels. Therefore, to establish a scalable process for the development of EBs, there is a need for dynamic cultivation under controlled mixing conditions. One approach employed a static system for an initial aggregation period of four days, followed by a period in dynamic culture in spinner flasks, to successfully achieve the bulk production of cardiomyocytes from differentiating mESCs (Zandstra *et al.*, 2003).

Another dynamic approach found to be highly effective for hESCs is to generate and culture EBs within rotating cell-culture systems (Gerecht-Nir *et al.*, 2004a). These bioreactors provide exceptionally supportive environments for the cultivation of hESCs: minimal hydrodynamic damage to incipient EBs; reduced opportunity for EB fusion and agglomeration (the speed of rotation may be increased according to EB size); and the uniform growth and

**FIG. 32.3.** Vascular differentiation of hES cells. Immunofluorescence analysis of mesodermal cells cultured in the presence of (A) hVEGF165 reveals expression of EC markers such as Dil-Ac-LDL and von Willebrand factor. (B) Similar analysis of cells cultured in the presence of hPDGF-BB reveals expression of VSMC markers such as SMA, calponin, and SM-MHC. Scale bars = 100  $\mu$ m. Figure adapted from Gerecht-Nir *et al.*, 2003.

differentiation of EBs in three dimensions, as they oscillate and rotate evenly (Fig. 32.3A). hESCs cultured within these systems formed aggregates after 12 h and were smaller and more uniform in size and evenly rounded, due to minimal agglomeration; the yield of EBs was threefold higher than that measured for static cultures. Also, dynamically formed EBs exhibit steady and progressive differentiation, with cyst formation and elaboration of complex structures such as neuro-epithelial tubes, blood vessels, and glands, as observed in statically formed EBs (Gerecht-Nir *et al.*, 2004a) (Fig. 32.3B). Although still an area of active research, these technologies have demonstrated the potential of engineering for the development of scalable technologies to expand ESCs for research and therapies.

### III. DIRECTED DIFFERENTIATION

Perhaps the biggest challenge in using ESCs in clinical applications is the lack of knowledge for directing their differentiation ability. For example, although ESCs have been shown to generate cells of hematopoietic, endothelial, cardiac, neural, osteogenic, hepatic, and pancreatic tissues, it has been very difficult to achieve uniform and predictable differentiation into these tissues. This lack of homogeneous differentiation may be attributed to the intrinsic property of ESCs to differentiate stochastically in the absence of proper temporal and spatial signals from the surrounding micro-environment. In this section we describe some of the current approaches used to direct the differentiation of ESC and give examples of their use.

#### Genetic Reprogramming

This approach includes the introduction of specific gene(s) into hESCs, which enable the production (by

enhancement or selection) and propagation of specific cell type populations. Different techniques for knock-in and knockout genes into hESCs were already established. Transfection of undifferentiated hESCs with specific plasmid was established using either chemical reagents or electroporation. The latter was further shown to be useful for the generation of homologous recombination events (Zwaka and Thomson, 2003). Another technique is the introduction of transgenes into hESCs with self-inactivated lentiviruses. This transduction technique was shown to be efficient, with sustained expression in undifferentiated hESCs as well as in hESCs that undergo differentiation (Gropp *et al.*, 2003; Ma *et al.*, 2003). However, using adenoviral and adeno-associated viral vectors, both undifferentiated and differentiated hESCs were successfully infected (Smith-Arica *et al.*, 2003). Another approach, which uses genetic manipulation, is the introduction of suicidal genes, permitting the ablation of the cells if necessary (Fareed and Moolten, 2002). Using this approach, hESCs were transfected to express the *Herpes simplex* virus thymidine kinase gene, which renders them to ganciclovir (Schuldiner *et al.*, 2003).

Genetic techniques can be used to generate positive or negative regulators. The positive regulators include the constitutive or controlled expression of transcription factors that have been shown to derive the differentiation into particular tissues. For example, the overexpression of Nurr transcription factor has been shown to increase the frequency of ESCs that differentiate into functional neural cells (Kim *et al.*, 2002). Alternatively, the negative regulators could be incorporated to induce the apoptosis of cells that differentiate to varying pathways. For example, neomycin selection and suicide genes that are activated by certain transcription factors can be used (Soria *et al.*, 2000). Clearly, these tech-

niques will benefit from further understanding of the inner workings of transient cells and a knowledge of the differentiation pathways and lineages. Further analysis into stem cell and progenitor hierarchy through high-throughput analysis of gene and protein profiles should accelerate this process. Despite the power of these approaches, one potential concern is that the genetic modifications may make the cells unsuitable for transplantation.

### Microenvironmental Cues

Another approach to direct ESC differentiation is through the use of microenvironmental cues that have been shown to be important in regulating adult and ESC fate decisions. During development, inner cell mass cells are exposed to a series of tightly regulated microenvironmental signals. However, in tissue culture much of the complex expression patterns and spatial orientation of this signaling can be lost. Currently, ESCs are grown in their primitive state as aggregated colonies of cells. To stimulate differentiation, two main methods have been examined. In one method, differentiated cells are derived from EBs. EBs can be formed from either single-cell suspensions of ESCs or from aggregates of cells. EBs mimic the structure of the developing embryo and recapitulate many of the stages involved during its differentiation, and clonally derived EBs can be used to locate and isolate tissue-specific progenitors. EBs initiate many developmental processes and create suitable conditions for differentiation of cells into all three germ layers and are generally formed through suspension or hanging drop methods. Alternatively, ESCs may be cultured in 2D monolayers and induced to differentiate. In general, differentiation of ESCs in EBs produces a wider spectrum of cell types, due to the EBs' ability to better mimic the temporal pattern of cell differentiation as seen in the embryo. In some applications the combined use of EBs and adherent cultures has resulted in better cell yields. For example, to induce ESCs to differentiate to cardiomyocytes, an EB formation in suspension cultures was followed by a differentiation in adhesion cultures. This was shown to optimize the percentage of cells that give rise to cardiomyocytes (Guan *et al.*, 1999; Klinz *et al.*, 1999). Similarly, the production of hepatocytes has been shown to be induced by first culturing the cell in EBs and then in 2D cultures (Hamazaki *et al.*, 2001).

One of the tissues that has been the focus of much study regarding ESC differentiation is neural tissue. Neural progenitor cells were isolated from hESCs that showed positive immunoreactivity to neuron-specific antigens, responded to neurotransmitter application, and presented voltage-dependent channels in the cell membrane (Carpenter *et al.*, 2001; Schulz *et al.*, 2003; Zeng *et al.*, 2004; Zhang *et al.*, 2001). Highly enriched cultures of neural progenitor cells were isolated from hESCs and grafted into the stratum of parkinsonian rats (Ben-Hur *et al.*, 2004). The grafted cells differentiated *in vivo* into dopaminergic neurons and partially corrected behavioral deficits in the

transplanted animals. A subsequent study showed that hESCs implanted in the brain ventricles of embryonic mice can differentiate into functional neural lineages and generate mature, active human neurons that successfully integrate into the adult mouse forebrain (Muotri *et al.*, 2005). Oligodendrocytes and their progenitors were also isolated in high yield from hESCs (Nistor *et al.*, 2005). Transplantation of these cells into animal models of dysmyelination resulted in integration, differentiation into oligodendrocytes, and compact myelin formation, demonstrating that these cells displayed a functional phenotype.

ESCs have also been shown to give rise to functional vascular tissue. Early vascular progenitor cells isolated from differentiating mESCs were shown to give rise to all three blood vessel cell components: hematopoietic, endothelial, and smooth muscle cells (Yamashita *et al.*, 2000). Once injected into chick embryos, these vascular progenitors differentiated into endothelial and mural cells and contributed to the vascular development. Using similar protocol, differentiation into endothelial and smooth muscle cells was achieved with hESCs (Gerecht-Nir *et al.*, 2003, Fig. 32.4). Our group has shown that hESCs can differentiate into endothelial cells, and isolated these cells using platelet endothelial cell adhesion molecule-1 antibodies (Levenberg *et al.*, 2002). *In vivo*, when transplanted into immunodeficient mice, the cells appeared to form microvessels. Furthermore, it has been shown that monkey ESCs can give rise to endothelial cells when the embryonic cells were exposed to a medium containing different growth factors. The isolated cells were able to form vascular-like networks when implanted *in vivo* (Kaufman *et al.*, 2004). Endohemato progenitor cells have been isolated from hESCs that presented hematopoietic (L. Wang *et al.*, 2004) or endothelial cells competency. hESCs have been reported to differentiate into hematopoietic precursor cells when cocultured with bone marrow and endothelial cell lines (Kaufman *et al.*, 2001). When these precursor cells are cultured on semisolid media with hematopoietic growth factors, they form characteristic myeloid, erythroid, and megakaryocyte colonies.

Cardiomyocytes have been also isolated from hES cells for the treatment of cardiac diseases. Beating cells were observed after one week of culture under differentiation conditions, increased in numbers with time, and could retain contractility for over 70 days (C. Xu *et al.*, 2002). The beating cells expressed markers characteristic of cardiomyocytes, such as cardiac  $\alpha$ -myosin heavy chain, cardiac troponin I and T, atrial natriuretic factor, and cardiac transcription factors GATA-4, Nkx2.5, and MEF-2. In addition, cardiomyocytes isolated from hES cells expressed sarcomeric marker proteins, chronotropic responses, and ion channel expression (Mummery *et al.*, 2003). Electrophysiology demonstrated that most cells resembled human fetal ventricular cells.

Insulin-producing  $\beta$ -cells were also generated from hESC. These cells were observed through the spontaneous

**FIG. 32.4.** Human EB formation in a rotating cell-culture system (Adapted from Gerecht-Nir *et al.*, 2004a). (A–B) Haematoxylin- and eosin-stained sections of EBs generated after one month in rotation culture, showing the formation of (A) a small and relatively homogenous population of human EBs and (B) a variety of cell types, such as epithelial neuronal tubes (dashed arrows) and blood vessels (solid arrows). Scale bars = 100  $\mu\text{m}$ .

differentiation of hESC in adherent or suspension culture conditions (Assady *et al.*, 2001) and in medium containing growth factors (Segev *et al.*, 2004). Reverse transcription-polymerase chain reaction detected an enhanced expression of pancreatic genes in the different cells (Segev *et al.*, 2004). Immunofluorescence and *in situ* hybridization revealed high percentages of insulin-expressing cells (Segev *et al.*, 2004).

Recently there has been great interest in examining the osteogenic potential of ESCs, derived from both mice and humans. Human hESCs can differentiate into osteogenic cells with the same media supplements that are used to differentiate adult mesenchymal stem cells. Our group showed that culturing hESC without EBs leads to over a sevenfold increase in the number of osteogenic cells and to spontaneous bone nodule formation after 10–12 days (Karp *et al.*, 2005). In contrast, when hESC were differentiated as EBs for five days, followed by plating of single cells, bone nodules formed after four weeks only in the presence of dexamethasone.

### 3D Versus 2D Cell Culture Systems

ESCs can differentiate into complex 3D tissue structures. To study this phenomenon *in vitro*, 3D culture systems are necessary. The scaffold may act as a temporary extracellular matrix (ECM) providing physical cues for cell orientation, spreading, differentiation, and the remodeling of tissue structures (Ferreira *et al.*, 2007). For example, our group showed that the culture of hESCs in poly(lactic acid-co-glycolic acid) (PLGA) scaffolds in specific media containing transforming growth factor  $\beta$ , activin-A, or insulin-like growth factor induced the differentiation of the cells into 3D structures with characteristics of developing neural tissues, cartilage, or liver, respectively (Levenberg *et al.*, 2003). It was also demonstrated that the 3D environment created by cell encapsulation in Matrigel failed to support hESC growth and 3D organization, likely due to the fact that this gel was unable to resist the force of cell contraction. Furthermore, when these cells were cultured in PLGA and poly(lactic acid) (PLA) scaffolds in the presence of medium containing nerve growth factor and neurotrophin 3, enhanced numbers of neural structures were observed (Levenberg *et al.*, 2005a). In another study, the culture of ESCs in a 3D collagen scaffold,

stimulated with exogenous growth factors and hormones, led to the differentiation of the cells into hepatocyte-like cells. These cells were characterized by the expression of liver-specific genes and synthesis of albumin, and the differentiation pattern observed compared favorably to cells differentiated in a 2D system. It was also reported that the differentiation of rhesus monkey ESCs in 3D collagen matrixes was different from that in monolayers (S. S. Chen *et al.*, 2003). Alginate scaffolds were also used for the differentiation of hESCs (Gerecht-Nir *et al.*, 2004b). These scaffolds induced vasculogenesis in encapsulated cells to a larger extent than cells grown in bioreactors. Tantalum scaffolds also increased the differentiation of mESCs into hematopoietic cells as compared to traditional 2D cultures (Liu and Roy, 2005).

### High-Throughput Assays for Directing Stem Cell Differentiation

Today, chemists and engineers are equipped with tools to be able to synthesize molecules and test their effects on cells in a high-throughput manner. For example, libraries of small molecules, polymers, and genes have been generated and used to screen candidate molecules to induce osteogenesis (Wu *et al.*, 2002) and cardiomyogenesis (Wu *et al.*, 2004) in ESCs as well as the dedifferentiation of committed cells (S. B. Chen *et al.*, 2004). The use of chemical compound libraries may provide a method of addressing the complexities associated with native microenvironments by directing cell behavior through interacting with transcription factors and cell fate regulators.

Micro-scale technologies can miniaturize assays and facilitate high-throughput experimentation and therefore provide a potential tool for screening libraries. Recently, robotic spotters capable of dispensing and immobilizing nanoliters of material have been used to fabricate microarrays, where cell–matrix interactions can be tested and optimized in a high-throughput manner. For example, synthetic biomaterial arrays have been fabricated to test the interaction of stem cells with various extracellular signals. In this approach thousands of polymeric materials were synthesized and their effect on differentiation of hESCs (Anderson *et al.*, 2004) and human mesenchymal stem cells (hMSCs) (Anderson *et al.*, 2005) evaluated. These interactions have led

to unexpected and novel cell–material interactions. Although the molecular mechanisms associated with the biological responses have yet to be clarified, such technology may be widely applicable in cell-microenvironment studies and in the identification of cues that induce desired cell responses. Also, the materials that yield desired responses could be used as templates for tissue-engineering scaffolds. Such an approach is a radical change from traditional methods of developing new biomaterials, where polymers have been individually developed and tested for their effect on cells.

In addition to analyzing synthetic-material libraries, the effect of natural ECM molecules on cell fate can be evaluated in a high-throughput manner. In one example, combinatorial matrices of various natural extracellular matrix proteins were tested for their ability to maintain the function of differentiated hepatocytes and to induce hepatic differentiation from murine ESCs (Flaim *et al.*, 2005).

Cell arrays have been used to pattern stem cells on 2D substrates. Arrays of cells can be used to localize and track individual cells, enabling clonal analysis of stem cell fates. For example, clonal populations of neural stem cells were immobilized within microfabricated structures, and their progeny were tracked using real-time microscopy, yielding information about cellular kinetics and cell fate decisions in a high-throughput manner (Chin *et al.*, 2004). Using this approach, it is possible to study the response of individual stem cells to various microenvironmental signals.

Cell patterning on geometrically defined shapes has been used to study the effects of cell shape on various cell fate decisions. As cells adhere onto micropatterned substrates, they align themselves to the shape of the underlying adhesive region. This shape change induces changes in the cytoskeletal features and has been shown to influence apoptosis, proliferation (Chen *et al.*, 1997), and stem cell differentiation. When hMSCs were patterned on fibronectin islands of various sizes, cells on large islands adhered and flattened, while cells on small islands generated spherically shaped cells. As these cells were stained for differentiation markers, it was observed that the spread cells generated osteoblasts and spherical cells gave rise to adipocytes (McBeath *et al.*, 2004). Further elucidation of the molecular mechanisms indicated that cell shape regulated the activation of the RhoA pathway, demonstrating that mechanical stresses can be crucial for directing stem cell differentiation. Therefore, controlling the cellular microenvironment using micropatterning may be used for directing cell fate for tissue-engineering applications.

It is known that mechanical forces affect the differentiation and functional properties of many cell types. Thus, mechanical stimuli may be required to direct the differentiation of ESCs. Understanding the effects of mechanical stimuli on ESC differentiation is still in its infancy, but tissue-engineering systems are already being developed that incorporate the effects of mechanical forces. For example, functional autologous arteries have been cultured

using pulsatile perfusion bioreactors (Niklason *et al.*, 1999). Thus the use of mechanical stimuli may further enhance the ability of these cells to respond to exogenous signals. Other environmental factors that may be required include electrical signals. Hopefully, with time such techniques will allow for the development of ESC-based tissue-engineering applications. The design of bioreactors that control the spatial and temporal signaling that induces ESC differentiation requires further collaborative efforts between engineers and biologists.

#### IV. ISOLATION OF SPECIFIC PROGENITOR CELLS FROM ESCs

Although hESCs can generate specific functional cell types from all three germ layers, it is typically not possible to differentiate the cells directly in culture and obtain pure cell populations. Isolation of a specific differentiated population of cells for transplantation will eliminate the presence of undifferentiated hESC, which have tumorigenic potential, and allow for efficient use of the various cell populations for therapeutic purposes. With the exception of a few cases where the enrichment of cells of interest was almost fully achieved (Ben-Hur *et al.*, 2004; Nistor *et al.*, 2005; Zeng *et al.*, 2004), the protocols adopted for the differentiation of hESCs do not yield pure cell populations. Therefore, there is a need for suitable techniques to isolate desired cells from a heterogeneous population of cells (Table 32.1). One approach is to isolate specific cells by using cell surface markers by fluorescence-activated cell sorting (FACS). In this case, the initial population of cells is immunostained by a single marker or a combination of different markers and the desired cell type isolated by FACS. Part of the initial population of cells is also labeled with isotype controls to gate the populations. The use of FACS yields pure populations of cells and allows one to select cells using different markers (L. Wang *et al.*, 2004). However, the intense flows in this technique may hamper the final cell survival.

Magnetic immunoselection has been used very often to isolate specific differentiated cells (Carpenter *et al.*, 2001; Kaufman *et al.*, 2001; Vodyanik *et al.*, 2005). Initially, the cells are labeled with relevant cell surface antibodies conjugated with magnetic beads. The magnetically labeled cells are then separated from the other ones by means of a magnetic column. The purity of isolated cells is generally higher than 80% (Vodyanik *et al.*, 2005). Although the purity achieved is slightly lower than the one obtained by FACS, the magnetic selection is generally less harmful to the cells than FACS. Another potential method for cell isolation is through reporter gene knock-in modifications (Lavon *et al.*, 2004). For example, to trace hepatic-like cells during differentiation of hESCs in culture, a reporter gene expressed under the control of a liver-specific promoter was used (Lavon *et al.*, 2004). For that purpose, hESCs underwent stable trans-

**Table 32.1.** Summary of methodologies to isolate specific lineages from hES cells

<i>Cell type</i>	<i>Methodology followed to isolate specific lineages</i>	<i>Cell lines</i>	<i>Reference</i>

fection with eGFP fused to the albumin minimal promoter sequence. This methodology allowed one to follow the differentiation pattern of hESCs into hepatic-like cells and to isolate those cells by FACS using the fluorescence of eGFP.

Isolation of a specific differentiated population of cells may also be accomplished by means of mechanical/enzymatic separation of cells exhibiting specific morphology, functional activity, or adhesion to a substrate. For example, cardiomyocytes have been isolated by dissecting contracting areas in embryoid bodies and dissociating those areas using collagenase (Kehat *et al.*, 2003). Oligodendroglial cells were isolated from stem cell aggregates that adhered to a specific substrate (Nistor *et al.*, 2005). In addition, neuroepithelial cells were isolated from embryoid bodies attached to a tissue culture–treated flask by using dispase (Zhang *et al.*, 2001). This enzyme selectively detached neuroepithelial islands from the embryoid bodies, leaving the surrounding cells adherent.

## V. TRANSPLANTATION

The first application of stem cells as a cellular replacement therapy is associated with bone marrow transplantation and blood transfusion, in which donor hematopoietic stem cells repopulated the host's blood cells (Till and McCulloch, 1980). Specific cell types from ESC can be an important cell-based therapy for numerous diseases, includ-

ing diabetes mellitus, Parkinson's disease, traumatic spinal cord injury, liver failure, muscular dystrophy, bone, vascular, and heart diseases, among others. Despite the significant advances in the use of mESC to treat several disease models (Verfaillie *et al.*, 2002), in the case of hESC, few studies have reported the *in vivo* functionality of differentiated cells. In most cases the cells are injected in a disease area and the functionality of those cells evaluated by immunohistochemistry and behavior tests. For instance, partial functional recovery of a mouse model of Parkinson's disease after injection of hESC-derived neural progenitor cells has been reported (Ben-Hur *et al.*, 2004). Moreover, the transplantation of oligodendroglial progenitor cells obtained from hESC in the *shiverer* model of dysmyelination resulted in integration, differentiation into oligodendrocytes, and compact myelin formation (McDonald and Howard, 2002).

Despite the ability of stem cells to differentiate to cells with the phenotypic and morphological structure of desired cell types, there has been very few scaffold-based tissue-engineering studies that use ESCs. ESCs may be differentiated in culture and desired cell types selected and subsequently seeded onto scaffolds. Ideally, this scaffold provides the cells with a suitable growth environment, optimum oxygen and nutrient transport properties, good mechanical integrity, and a suitable degradation rate. The scaffold brings the cells in close proximity and thereby

enhances self-assembly and formation of tissue structures. Ultimately, *in vitro* differentiated constructs can potentially be used directly for transplantation.

For a tissue-engineering approach, the scaffold could comprise either synthetic or natural material or a composite of the two. Common scaffold materials include synthetic materials, such as hydroxyapatite, calcium carbonate, PLA, and poly(glycolic acid) (PGA), PLGA, and poly(propylene fumarate), or natural materials, such as collagen, Matrigel, and alginate. Natural materials are typically more favorable to cell adherence, while the properties of synthetic materials, such as degradation rate, mechanical properties, structure, and porosity, can be better controlled (Langer and Vacanti, 1993).

We have used a tissue-engineering approach to study the behavior of hESC-derived endothelial cells under *in vivo* conditions (Levenberg *et al.*, 2002). Human ESC-derived endothelial cells that were seeded onto highly porous PLGA biodegradable polymer scaffolds formed blood vessels that appeared to merge with the host vasculature when implanted into immunodeficient mice. In addition, those cells were able to vascularize constructs containing myoblasts to yield vascularized skeletal muscle (Levenberg *et al.*, 2005b). Osteoblast-like cells derived from hESC were also transplanted into an animal model by using a poly(D,L-lactide) scaffold. After 35 days of implantation, regions of mineralized tissue could be identified within the scaffold by Von Kossa staining and expression of human osteocalcin (Bielby *et al.*, 2004).

### Transplantation and Immune Response

One of the major obstacles for the successful transplantation of differentiated cells from hESCs is the potential immunogeneity of these cells. Because long-term immunosuppressive therapy would limit successful clinical applications, the creation of immunologic tolerance would enable stem cell-derived therapy. Methods currently under development and examination include (a) the establishment of hESC-line banks large enough to represent the majority of tissue types; (b) nuclear reprogramming the cells to carry patient-specific nuclear genome (therapeutic cloning); (c) creation of a “universal cell” suitable for all patients by manipulating the major histocompatibility complex (MHC) (Drukker *et al.*, 2002); (d) deletion of genes for immune-response proteins using homologous recombination (as mentioned earlier); and (e) the generation of hematopoietic chimerism, to create the required tolerance for tissues or cells derived from it (Bradley *et al.*, 2002). The latter was shown to be specifically useful with rat embryonic-like stem cells, where their injection into full MHC-mismatched rats resulted in permanent engraftment (Fandrich *et al.*, 2002).

Therapeutic cloning, or somatic cell nuclear transfer (SCNT), the process through which Dolly the sheep was cloned in 1997, might be an important tool to create hESCs from patient-specific genome, thus preventing immunore-

**FIG. 32.5.** Schematic diagram of the therapeutic cloning process to generate immunologically compatible tissues.

jection issues (Hwang *et al.*, 2004) (Fig. 32.5). This is very important for the application of hES cells in the area of tissue engineering where a transplantable population of cells can be generated with genes that are derived only from the original donor nucleus (i.e., from the patient). Studies to date have demonstrated that cells derived from SCNT can be expanded in culture and can organize into tissue structures after transplantation *in vivo* in combination with biodegradable scaffolds. However, before SCNT research can be translated into human therapies, the reliability and efficiency of the overall process need to be improved. Additional challenges include preventing alterations in gene expression and finding a sufficient source of oocytes.

Closed tissue-engineering systems, such as the use of immunoisolation systems, may overcome the immunological incompatibility of the tissue. Thus, immunoisolation of cells may prove to be particularly useful in conjunction with ESCs to overcome the immunological barrier associated with the ESC-based therapies. In such systems, cells may be immobilized within semipermeable polymeric matrices that provide a barrier for the immunological components of the host. Such semipermeable membranes are permeable to nutrients and oxygen while providing a barrier to immune cells, antibodies, and other components of the immune system (Lim and Sun, 1980; Uludag *et al.*, 2000). Within these systems, the implants can be either implanted into the patient or used as extracorporeal devices. Closed

tissue-engineering systems have been used particularly for the treatment of diabetes (Chicheportiche and Reach, 1988; Sefton *et al.*, 2000; Zekorn *et al.*, 1992), liver failure (Chandy *et al.*, 1999; Uludag and Sefton, 1993; L. Wang *et al.*, 2000), and Parkinson's disease (Aebischer *et al.*, 1991; Esposito *et al.*, 1996; Vallbacka *et al.*, 2001; Y. Wang *et al.*, 1997). For example, ESC-derived  $\beta$ -cells that can respond to insulin or dopamine-producing neurons can be used in clinics without fear of rejection. In addition, closed systems protect the host against potentially tumorigenic cells because it limits the cells within the polymeric barrier. Currently, engineering and biological limitations, such as material biocompatibility, molecular weight cutoff, and the immune system's reaction to shed antigens by the transplanted cells, are some of the challenges that prevent these systems from widespread clinical applications.

## VI. FUTURE PROSPECTS

Despite significant progress in the field of tissue engineering and ESC biology, there are number of challenges that provide a barrier to the use of ESCs for tissue engineering. These challenges range from understanding cues that direct stem cell fate, to engineering challenges on scale-up, to business questions of feasibility and pricing.

Although the derivation of hESCs from the ICM of preimplantation blastocysts has become a standard procedure and has been performed in a variety of laboratories, live human embryos must be destroyed in the process, which is ethically problematic and has led to a variety of responses from around the world. However, recent reports show that it is possible to isolate embryonic stem cells without destroying the embryo (Chung *et al.*, 2006).

In August 2001, President Bush announced a policy in the United States to allow federal funding for research using an existing 60 lines of embryonic stem cells but prohibited funding for the creation of new lines or for using cells obtained from surplus embryos produced in fertility clinics. Aside from this decision to eliminate unregulated private creation of ESC lines, the existing federally approved lines are neither sufficiently available nor adequate for human therapies. Specifically, all of the approved stem cell lines were prepared using mouse cells and thus pose a risk of contaminating human subjects. However, advancements since 2001 have established methods to culture hESCs without mouse feeder layers. Interestingly, it has recently been proposed that a common ground for pursuing hESC research may exist through assessing the death of a human embryo in the ethical context surrounding organ donation. Specifically, Landry and Zucker (2004) argue that a significant fraction of embryos generated for *in vitro* fertilization undergo irreversible arrest of cell division and thus can be considered as organismically dead yet can be used as normal donors of blastomeres. Thus donation of these embryos could ethically be considered analogous to the donation of essential organs from cadavers. Although crite-

ria for determining the irreversible arrest of cell division have yet to be defined, it will certainly be interesting to see if these theories can be experimentally established and how these arguments will fare with those who currently oppose hESC research.

Synthetic scaffolds that support tissue growth by serving as the extracellular matrix for the cells do not represent the natural matrix molecules associated with each cell type and tissue. ESCs and their progeny during development reside in a dynamic environment; thus a scaffold should be designed to mimic the signaling and structural elements in the developing embryo. The use of "smart" scaffolds that release particular factors and/or control the temporal expression of various molecules released from the polymer can help induce differentiation of ESCs within the scaffolds (Richardson *et al.*, 2001). For example, dual delivery of vascular endothelial growth factor (VEGF)-165 and platelet-derived growth factor (PDGF), each with distinct kinetics, from a single, structural polymer scaffold resulted in a mature vascular network (Richardson *et al.*, 2001). An alternative approach to modify the surface exposed to the cells is to immobilize desired ligands onto the scaffold. For example, RGD peptides, the adherent domain of fibronectin, can be incorporated into polymers to provide anchorage for adherent cells.

Another difficulty with the current materials is their lack of control over the spatial organization within the scaffold. Spatial patterning is necessary to create tissues that resemble the natural structure of biological tissues. In the direct cell-patterning system, cells can be seeded into the scaffold at particular regions within the cells. For example, the direct attachment of two different cell types on the different sides of the scaffold has been used to generate cells of the bladder. Cell-patterning techniques such as those that have been developed for soft lithography for controlled coculture of hepatocytes and fibroblasts could be scaled up to tissue-engineering scaffolds to allow for more controlled and complex direct patterning.

## VII. CONCLUSIONS

A number of challenges remain in making ESC-based therapy clinically viable. These include directing the differentiation of ESCs (i.e., using controlled microenvironments or genetic engineering) to ensure their safety (i.e., by eliminating tumorigenicity), to ensure that the differentiated cells integrate functionally into the body, to ensure their immune compatibility with the patient, and to improve the cost and feasibility of cell-based therapies. Each of these challenges is an area of active research that must be validated and optimized. In particular, since ESCs can give rise to many different cell types, solving these challenges for the various possible tissue types will be a major undertaking. Further research is required to control and direct the differentiation of ESCs. If done in parallel with developing methods to generate tissues of various organs, this may

lead to realizing the ultimate goal of tissue engineering. We are getting close to the day when ESCs can be manipulated in culture to produce fully differentiated cells that can be used to create and repair specific organs. Clearly, significant challenges remain, and the ability to overcome these diffi-

culties is not confined to any single scientific discipline but, rather, involves an interdisciplinary approach. Innovative approaches to solve these challenges could lead to improved quality of life for a variety of patients who could benefit from tissue-engineering approaches.

## VIII. ACKNOWLEDGMENTS

The authors would like to acknowledge funding from NIH (HL60435, HL076485) Juvenile Diabetes Research Foundation (G V-N, Fellowship to SG), NSF, the Draper Laboratories, the Centre for Integration of Medicine and Innovative

Technology, the Coulter Foundation, the Institute for Soldier Nanotechnology (DAAD-19-02-D-002), and Fundação para a Ciência e Tecnologia (grant SFRH/BPD/14502/2003 to L.F).

### I. INTRODUCTION

The years since the mid-1990s have witnessed the emergence of stem cell-based tissue engineering as a means to restore normal structure and function to tissues lost to trauma or disease. Successful application will rely on (1) further characterization of the biological properties of postnatal stem cells (what they can and cannot do); (2) optimization of their isolation and *ex vivo* expansion; (3) formulation of appropriate scaffolds and carriers, which may also include growth factors; (4) development of more advanced bioreactors to create tissues with appropriate biomechanical properties; and (5) determination of mechanisms by which to mobilize and activate endogenous stem cells. This chapter highlights these aspects of stem cell-based tissue engineering and presents examples of current approaches and applications.

At first inception, tissue engineering was based on the use of natural or synthetic scaffolds seeded with organ-specific cells *ex vivo*. This approach was somewhat distinct from guided tissue regeneration, which utilized scaffolds and/or bioactive factors to encourage local cells to repair a defect *in situ*. These two approaches are now merged in the current field of tissue engineering, which encompasses multiple and diverse disciplines to use cells, materials, and bioactive factors in various combinations to restore and even improve tissue structure and function. Stem cell-based tissue engineering represents a major turn in the conceptual approach to reconstruction of tissues. By expanding the repertoire of available cells, of potential targets, and of technological means of generating functional tissues *ex vivo* and

above all by making it possible (or promising) to engineer tissues that otherwise would not be amenable to recreation, advances in stem cell biology are having a profound impact on tissue engineering in general. In many cases, tissue engineering seems to have more use for stem cells than does nature itself. This is especially apparent in the case of stem cells derived from tissues with low turnover or no apparent turnover at all. If neural stem cells were able to repair the loss of dopaminergic neurons in the intact brain *in vivo*, there would be no Parkinson's disease for which to envision stem cell-based therapies. Dental pulp stem cells do not regenerate primary dentin *in vivo*, but vast numbers of cells can be made from the pulp of a single extracted tooth to generate copious amounts of new dentin. Current definitions of stem cells in fact include a technological dimension in many cases (a cell that can be expanded *ex vivo* and bent to the generation of differentiating cells). Importantly, the two neighboring fields of cell therapy (reconstruction of functional tissues *in vivo* using cells) and tissue engineering proper (reconstruction of functional tissues using cells and something else) merge significantly once a stem cell angle is adopted for either, not only with respect to the ultimate goals, but also to several biotechnological aspects.

### II. RESERVOIRS OF POSTNATAL STEM CELLS

Because of ethical constraints and for ease of harvest and control, current approaches to stem cell-based tissue

engineering rely largely on the use of postnatal stem cells. Once restricted to a handful of constantly (and rapidly) self-renewing tissues, such as blood, skin, and the gastrointestinal tract, the repertoire of postnatal stem cells has expanded to include perhaps every single tissue in the body, regardless of the rate of tissue turnover or ability to regenerate (reviewed in Preston *et al.*, 2003; Wagers and Weissman, 2004). Not all of these tissue-specific stem cells, however, are equally accessible for safe harvest or available in sufficient quantity (or amenable for *ex vivo* expansion) to generate the number of cells needed for tissue regeneration. However, lessons on the dynamics of tissue homeostasis (growth and turnover) that can be learned from these cells have an obvious impact on the design of future tissue-engineering strategies nonetheless. In addition, mechanisms whereby postnatal cells maintain differentiated functions in tissues and organs are relevant to future embryonic stem cell-based approaches and can only be learned from postnatal cells (Wagers and Weissman, 2004).

### Plasticity and Transdifferentiation – Implications for Tissue Engineering

The recent clamor about the potential *plasticity* (the ability of a cell to convert from one type to another) and *transdifferentiation* (conversion of a cell from one lineage to another) of certain classes of postnatal stem cells unquestionably adds further questions (Moore and Quesenberry, 2003). Rigorous proof of true plasticity and transdifferentiation have been lacking in many reports and can only be demonstrated by the ability of a single (clonogenic) cell to form cells of multiple different phenotypes and which can be shown to function as those different cell types. Some would also add that conversion must be more than an isolated phenomenon; it must occur at a high frequency and be persistent or stable (reviewed in Lakshmipathy and Verfaillie, 2005; Pauwelyn and Verfaillie, 2006). Nonetheless, postnatal stem cell plasticity provides a new twist, once the perspective of usage for tissue reconstruction is directly addressed. It would be impractical, to say the least, to use neural stem cells for bone marrow transplantation; and a tissue engineer's enthusiasm for this unexpected finding may remain lukewarm. In contrast, deciding whether liver regeneration is successfully accomplished using previously unknown "hepatogenic" stem cells or transdifferentiation of hematopoietic stem cells (Lagasse *et al.*, 2000) or by reprogramming of a donor lymphocyte nucleus following cell fusion (Wang *et al.*, 2003) may not disrupt a tissue engineer's sleep, as long as the goal is met. Unquestionably, some examples of "unorthodox" differentiation of postnatal stem cells have been given (reviewed in Camargo *et al.*, 2004; Goodell, 2003; Wagers and Weissman, 2004). However, further investigation is needed to confirm not only the concept of postnatal stem cell plasticity, but specifically the technological aspects of its effective translation into clinical application, once proof of principle has been given. Even if

true plasticity is a rare event, analyzing the way it occurs may provide clues as to how better to manipulate cell populations to increase its frequency.

### Bone Marrow – A Source of Multiple Stem Cells

It has long been known that bone marrow is the home of at least two different types of stem cells, the hematopoietic stem cell (HSC, reviewed in Bryder *et al.*, 2006) and the skeletal stem cell (SSC, also known as the bone marrow stromal stem cell or "mesenchymal" stem cell; reviewed in Bianco and Robey, 2004), each able to reconstitute the hematopoietic and skeletal systems, respectively. Both systems are thought to be able to contribute differentiated cell types outside of their physiological progeny. Highly purified HSCs were reported to give rise to cardiomyocytes (Orlic *et al.*, 2001), as well as hepatocytes (Lagasse *et al.*, 2000) and a host of epithelial tissues (Krause *et al.*, 2001). Bone marrow stromal cells have been reported to generate functional cardiomyocytes *in vitro* (murine) (reviewed in Minguell and Erices, 2006) and to be capable of neural differentiation (reviewed in Phinney and Isakova, 2005). A rare subset of murine bone marrow cells (multipotential adult progenitor cells, MAPCs) have been reported to be almost as multipotent as ES cells (Jiang *et al.*, 2002). AC133 (CD133) positive endothelial progenitors are found in the marrow (Gehling *et al.*, 2000), and endothelial cells themselves may generate cardiomyocytes *in vitro* (Badorff *et al.*, 2003). Circulating, marrow-derived cells contribute to regeneration of skeletal muscle in response to injury (G. Ferrari *et al.*, 1998) and, in mouse models, of muscular dystrophy (Bittner *et al.*, 1999; Gussoni *et al.*, 1999). Donor-derived cells have also been detected in neuronal tissue, in newly formed vasculature, in the kidney, and even in the oral cavity following bone marrow or mobilized peripheral blood transplantation (reviewed in Poulosom *et al.*, 2002). Ideally, the identification of a single accessible site that would contain reservoirs of cells with pluri- and multipotentiality that are easily harvested in large quantities would mark a major advantage in tissue engineering. If substantiated, this wealth of observations would make bone marrow the central organ of tissue engineering and stem cell therapy (Fig. 33.1). However, much more investigation is needed in order to substantiate these preliminary findings to determine the true efficacy of bone marrow for treatment of such a broad spectrum of abnormalities (reviewed in Pauwelyn and Verfaillie, 2006).

## III. CURRENT APPROACHES TO TISSUE ENGINEERING

Tissue-engineering approaches to the regeneration of functional tissue using postnatal stem cells can be envisioned by three different scenarios: (1) expansion of a population *ex vivo* prior to transplantation into the host, (2) re-creation of a tissue or organ *ex vivo* for transplantation, and (3) design of substances and/or devices for *in vivo* acti-

**FIG. 33.1.** Bone marrow as a central source of postnatal stem cells. Bone marrow consists of at least two well-defined populations of postnatal stem cells, the hematopoietic stem cell (HSC) and the skeletal stem cell (SSC), both of which form numerous phenotypes within their cellular system but may also form cells outside of them. Multipotential adult progenitor cells (MAPCs) are a subset of bone marrow stromal cells and have been reported to form virtually all cell types in mouse. Endothelial precursors (AC133+) have recently been identified, and other types, such as a hepatocyte-like stem cell, may also exist. These remarkable findings, if verified, place bone marrow high on the list of tissues that are easily accessible in sufficient quantity for use in tissue engineering.

vation of stem cells, either local or distant, to induce appropriate tissue repair (Fig. 33.2). In all of these cases, considerable knowledge of the stem cell population's dynamics is required in order to predict and control their activity under a variety of different circumstances.

### Ex Vivo Culture of Postnatal Stem Cells

*Ex vivo* expansion of tissue- or organ-specific cells, either used alone or added to carriers and scaffoldings or with growth factors at the time of transplantation, has been the primary approach in tissue engineering to date. However, *ex vivo* expansion in a fashion that maintains an appropriate proportion of stem cells within the population is a significant hurdle that must be overcome. For example, in spite of enormous effort, the culture conditions for maintaining HSCs (let alone expanding their number) are as yet undefined. It is perhaps for this very reason that currently there are only a handful of examples in which *ex vivo* expanded postnatal stem cells are used successfully to restore structure and function. The key to successful expansion will lie in understanding cell proliferation kinetics (asymmetric versus symmetric division) (Morrison and Kimble, 2006; Sherley, 2002). The efficacy achieved by the use of *ex vivo* expanded populations, whether stem or more

committed in character, may also depend, at least in part, on the nature of the tissue under reconstruction. Within this context, the rate of tissue turnover most likely defines the rate of success. In tissues with a high rate of turnover, such as blood and skin, it is clear that long-term success depends on the persistence of a stem cell within the transplanted population. More committed progenitors may provide some short-term advantage; but without a self-renewing population, failure is ultimate. However, in tissues that turn over more slowly (e.g., bone), long-lasting benefit may be achieved with more committed populations of cells.

While optimizing culture conditions represents one hurdle, the issues of time and quantities represent others. In most cases, the amount of time required to generate the number of cells sufficient to repair defects induced by trauma or disease is on the order of weeks. In cases of trauma, this poses a large problem if the use of autologous stem cells is considered. For that reason, the use of allogeneic populations that could be used "off the shelf" from unrelated donors would be preferable, but this raises the issue of rejection, as in organ transplantation. Although it is suggested that some postnatal stem cells appear to escape from immune surveillance in allogeneic settings and are immunomodulatory (Le Blanc and Pittenger, 2005), definitive proof is lacking. Furthermore, differentiation of stem cells would imply the expression of a mature tissue-specific phenotype, including a complete histocompatibility profile (Fang *et al.*, 2004). Use of allogeneic cells would most likely require concomitant immunosuppressive therapy, which has its own list of side effects. Cotransplantation of allogeneic bone marrow to reconstitute the hematopoietic system has been proposed as a way of inducing tolerance (Weissman, 2005). Recent studies in organ transplantation in conjunction with bone marrow or mobilized blood transplantation after immune ablation indicate a substantial improvement in long-term survival. In this type of approach, allogeneic cells could be better envisioned, provided that a single donor is the source of cells for the tissue to be restored along with the immune system.

### Delivery of Stem Cells

Delivery of bone marrow or mobilized blood by systemic infusion for restoration of the hematopoietic system by HSCs is clearly an example of the efficacy of this method of delivery, but it is perhaps the only example. The success of systemic infusion is based primarily on the fact that in terms of physical structure, blood is a simple, fluid entity. Although bone marrow transplantation has been attempted for the delivery of nonhematopoietic cells to sites of injury, it is not yet clear that there is long-term survival and engraftment of such cells (reviewed in Pauwelyn and Verfaillie, 2006). Reconstruction of two- or three-dimensional structures requires different approaches. Currently, there are a number of clinical applications, or ones soon to emerge, for the delivery of cell populations orthotopically into a site for

**FIG. 33.2.** Current applications of postnatal stem cells in tissue engineering. While virtually all tissues in the body have cells with some regenerative capabilities, current postnatal stem cell-based strategies, or ones in the foreseeable future, rely on a relatively limited number of source tissues. Autologous bone marrow is currently in trial for myocardial regeneration. Most approaches utilize *ex vivo* expanded cell populations that are then delivered orthotopically in various combinations with bioactive factors and scaffolds, with skeletal and muscle regeneration. Generation of 2D and 3D structures *ex vivo* requires the use of bioreactors, in which cells are seeded onto scaffoldings and subjected to nutrient flow, bioactive factors, and mechanical forces to induce formation of functional tissue for transplantation.

tissue regeneration. In some cases, specific populations of cells are expanded *ex vivo* and delivered either alone or in conjunction with a natural or synthetic material. As important as it is to control the *ex vivo* behavior of the cell population, it is also important to take into consideration what the cells' response will be to the host environment. It is the host that must provide the signals that will dictate the differentiation if uncommitted populations are utilized. Furthermore, the recipient host tissue must also support the maintenance of the stem cell's niche, if not the creation of it *de novo*.

### Reconstruction of the Skeletal Tissues — Bone, Cartilage, and Teeth

After numerous preclinical studies in a variety of animal models, it was demonstrated that bone marrow stromal cells, when used in conjunction with appropriate carriers, could regenerate new bone in critical-sized defects that would never heal without intervention (reviewed in Bianco and Robey, 2001; Cowan *et al.*, 2005). A wide variety of carriers were tested, ranging from collagen sponges and syn-

thetic biodegradable polymers to synthetic hydroxyapatite derivatives, although, to date, none appear to be optimal (reviewed in El-Ghannam, 2005). A carrier that provides immediate stability, especially in the case of weight-bearing bones, and yet can be completely resorbed as new bone is formed and remodeled has not yet been fabricated. Nonetheless, a small number of patients were treated with *ex vivo* expanded bone marrow stromal cells (BMSCs) in conjunction with hydroxyapatite/tricalcium phosphate ceramic particles, with good outcome (Quarto *et al.*, 2001), and other clinical studies are in progress. In addition to healing segmental defects, BMSCs were also used to construct vascularized bone flaps. In cases where morbidity of the recipient site is an issue, it can be envisioned that a new bone rudiment could be grown elsewhere in the body and then transferred, with vasculature intact (Mankani *et al.*, 2001). More recently, adipose tissue was identified as a source of stem cells that also have the potential to differentiate into bone and cartilage, at least, and may be equally as multipotential as BMSCs (reviewed in Gimble and Guilak, 2003). Naturally, if these studies are further substantiated, fat would become

another prime source of easily accessible stem cells for tissue engineering (Parker and Katz, 2006).

Current cell-based therapy for the treatment of cartilage defects relies on growth of chondrocytes from a biopsy, followed by transplantation onto articular surfaces in conjunction with a periosteal flap (Brittberg *et al.*, 1994). While this procedure is practiced worldwide, long-term efficacy is questionable, and there is a clear need for better procedures. BMSCs and stem cells from adipose tissue are capable of forming cartilage in a test tube (Guilak *et al.*, 2004; Song *et al.*, 2004), but their use in the reconstruction of cartilage on articular surfaces will rely on inhibiting their further differentiation into hypertrophic chondrocytes. In addition, further development of suitable carriers that provide the appropriate microenvironment to maintain the cartilage phenotype and prevent hypertrophy is also required. Natural polymeric gels, such as hyaluronic acid, collagen, alginate, and chitosan, provide an adequate three-dimensional structure to maintain the chondrocyte phenotype, but these are not well modeled into specific shapes and have very poor biomechanical properties. For these reasons, synthetic biodegradable polymers, such as polylactic acid and polyglycolic acid, and mixtures of both that can be cross-linked and molded to form porous three-dimensional structures are thought to provide more adequate scaffolding and have been used to construct cartilage with predefined shapes (reviewed in Frenkel and Di Cesare, 2004; Kuo *et al.*, 2006). In designing constructs of stem cells and scaffolds, the differences between the elastic cartilages of the ear and the nose and articular cartilage must also be considered to ensure that tissues form with the appropriate biomechanical characteristics.

Using techniques developed for the isolation and characterization of bone marrow stromal cells, dental pulp from the permanent dentition was found to contain a population of stem cells (dental pulp stem cells, DPSCs) that has the ability to form copious amounts of primary dentin and a pulplike complex on *in vivo* transplantation with hydroxyapatite/tricalcium phosphate ceramic particles (Gronthos *et al.*, 2000). Stem cells are also present in the pulp of deciduous teeth (SHED, stem cells from human, exfoliated, deciduous teeth) that have a high proliferative capacity, and, in addition to forming dentin, they may be able to form other cell types (Miura *et al.*, 2003). Further characterization of their differentiation potential is under way. Cells isolated from the periodontal ligament re-create a PDL-like structure and form cementum when transplanted in conjunction with hydroxyapatite/tricalcium phosphate (Seo *et al.*, 2004). Based on these findings, reconstruction of structures in the craniofacial complex can be envisioned (reviewed in Robey, 2005; Robey and Bianco, 2006).

### Regeneration of Skeletal and Cardiac Muscle

Muscle contains a population of muscle-specific stem cells, the satellite cell (reviewed in Zammit *et al.*, 2006). Early attempts to use *ex vivo* expanded populations of allogeneic

myoblastic cells derived from satellite cells to correct muscular dystrophies were all uniformly unsuccessful, due to immunological responses of the host to allogeneic cells (and the expression of a foreign protein by the donor cells) and the inability of donor cells to repopulate extensively (Cossu and Mavilio, 2000). In other studies, bone marrow transplantation provided a cell that could participate in the formation of new myotubes in a muscle injury model (G. Ferrari *et al.*, 1998) and in a model of muscular dystrophy (Gussoni *et al.*, 1999); however, the level of incorporation of donor cells was very low. Recently, “mesenchymal” stem cells isolated from the synovial membrane and sharing resemblances with bone marrow–derived stromal cells have been shown to repair dystrophic muscle in the mdx mouse (De Bari *et al.*, 2003). Mesoangioblasts, which are blood vessel–associated stem cells, may also be useful in skeletal muscle regeneration (Sampaolesi *et al.*, 2003).

Although skeletal muscle cells are functionally quite distinct from cardiomyocytes, autologous myoblastic cells have been viewed as a potential therapy for the treatment of myocardial infarct. Initial results suggest that there is functional improvement (Menasche *et al.*, 2003), even though the mechanisms are unclear, due to recent evidence that engrafted cells are not electromechanically linked with recipient cells (Leobon *et al.*, 2003). The utility of autologous bone marrow for myocardial regeneration is also currently receiving a great deal of attention, based on studies that attribute the ability of HSCs and BMSCs to form cardiomyocytes and the ability of marrow-derived endothelial precursors to participate in the development of new blood vessels in a number of animal models (reviewed in Itescu *et al.*, 2003). Based on these encouraging findings, transendocardial injection for the treatment of ischemic heart failure using marrow-derived cells is being tested in a number of small clinical trials. Patients receiving an autologous bone marrow transplant in conjunction with cardiac bypass surgery (Perin *et al.*, 2003) and those receiving AC133+ endothelial precursor cells alone (Stamm *et al.*, 2003) are reported to have increased cardiac perfusion and enhanced ventricular function. Interestingly, it appears that the use of many cell types results in a substantial improvement of cardiac function (Murry *et al.*, 2006). Whether they engraft at a substantial level and in fact differentiate into cardiomyocytes remains to be proven (Orlic, 2005; Stamm *et al.*, 2006). It should be considered that within this context, clinical benefit may be conveyed by a “helper” effect on putative local progenitors or by improvement of perfusion following angiogenesis induced by transplanted endothelial progenitors. Considering the high prevalence of ischemic heart disease, further testing of this application is warranted.

### Ex Vivo Reconstructions — Cells, Scaffolds, and Bioreactors

The creation of tissues and even organs prior to transplantation is a rapidly expanding area of research. This approach relies on expanding cell populations on or in

either natural or synthetic scaffolds in a bioreactor. Whether natural or synthetic, scaffolds must be biocompatible, bioresorbable, and nonimmunogenic. Furthermore, they must also be instructive and dictate appropriate cell growth and differentiation, and they must support the recapitulation of a stem cell niche, which is essential for tissue renewal on transplantation. The most commonly used natural scaffolds include either individual purified extracellular matrix (ECM) proteins, such as collagen, fibronectin, and laminin (or peptides derived from them) or devitalized ECM from skin, submucosa of the small intestine, urinary bladder, and others, and they can be autologous, allogeneic, or even xenogeneic. Such devitalized ECMs contain not only the structural proteins (which also have other important biological activities) that define the three-dimensional organization of the tissue, but also the local repertoire of growth factors that are stored within them (reviewed in Gilbert *et al.*, 2006). Various chemical and nonchemical treatments have been applied to ECMs and their components in attempts to modify their biomechanical and immunological properties on transplantation, but these result in less-than-desirable effects due to inactivation of their conductive and inductive properties and inhibition of their resorption and replacement. If left unmodified, ECMs generally promote infiltration and proliferation of cells and differentiation *in vitro* and *in vivo* and are ultimately turned over on transplantation (reviewed in Badylak, 2002). Synthetic scaffolds are designed not only to mimic the biological properties of ECMs, but also to have enhanced material properties appropriate for a particular tissue. Polyglycolic acids, polyhydroxyalkonates, and hydrogels are the most common examples, and all can be manipulated to form a broad range of structures with varying degrees of porosity and rigidity (Hollister, 2005). Scaffolds can also be formulated to include morphogenetic and growth factors or even naked plasmid DNA to transduce ingrowing cells to produce these important factors, such that they can become as instructive as ECMs (reviewed in Hench and Polak, 2002).

In addition to having appropriate scaffolds, the ability to construct tissues and organs *ex vivo* depends on the design of appropriate bioreactors. The initial designs provided primarily nutrient flow through the developing tissue. However, many tissues grown under these circumstances fail to achieve the biomechanical properties required for tissue function *in vivo*. For example, the construction of blood vessels using a variety of biomaterials and cell populations using culture perfusion yields structures that histologically resemble native blood vessels. Yet when transplanted, these constructs failed, due to their inability to withstand changes in pressure. A substantial improvement in such constructs was achieved by subjecting the developing tissues to pulsatile flow conditions (reviewed in Levenberg, 2005). Perfusion-type bioreactors support the growth of tissue with only a nominal number of cell layers and are amenable to construction of relatively simple

structures. Construction of larger, more complex three-dimensional structures requires the development of even better bioreactors that will support cell survival to achieve a significant cell mass (reviewed in Martin *et al.*, 2004). Another critical aspect of using large constructs is the development of supporting vasculature. While constructs can be placed in vascular beds in some cases, it will be essential to design constructs that rapidly induce vascularization, perhaps by including the angiogenic factor, VEGF, or cells that produce it or even by including endothelial cells and their precursors, which tend to assemble themselves into primitive tubular structures that may allow for more rapid establishment of organ perfusion (reviewed in Griffith and Naughton, 2002).

Next to bone marrow transplantation, skin grafts perhaps provide the best example of the impact of postnatal stem cell biology on the success of cell-based tissue reconstruction. Although the use of *ex vivo* expanded keratinocytes for the generation of skin grafts was first brought to a clinical setting by the pioneering work of Green and coworkers (Green, 1989), persistent engraftment has not been routine. It is now recognized that both the expansion culture conditions in which the cells are grown and the scaffolding on which they are placed must support self-renewal of epidermal stem cells (cells that give rise to holoclones, as opposed to transiently amplifying meroclones or more differentiated paraclones) (Barrandon and Green, 1987). Expansion of keratinocyte populations on fibrin substrates was found to maintain the stem cell population and to improve long-term maintenance of skin grafts (Pellegrini *et al.*, 1999). A number of studies are now under way to molecularly engineer autologous epidermal stem cells to correct a gene defect causing severe blistering prior to generation of skin grafts (reviewed in S. Ferrari *et al.*, 2006). Currently, a number of commercial products are available (both autologous and allogeneic), some of which incorporate dermal fibroblasts in a collagen gel, which is then layered with *ex vivo* expanded epidermal cells (reviewed in Supp and Boyce, 2005). They provide coverage of severe wounds and are maintained while the recipient generates new skin. The standard starting material for establishing epidermal cultures is skin. However, recent evidence indicates that a stem cell located in the bulge region of the root sheet of hair follicles has the ability to form not only new follicles and sebaceous glands, but also interfollicular epidermis under certain circumstances (reviewed in Blanpain and Fuchs, 2005). These cells, which can be obtained non-invasively, are highly proliferative and have recently been used successfully to treat leg ulcers (Limat and Hunziker, 2002). Based on lessons learned from skin regeneration, stem cells in the limbus of the sclera and conjunctiva have been expanded in culture on fibrin substrates to generate sheets of epithelial cells able to reconstitute a damaged corneal surface, with dramatic beneficial clinical results (reviewed in Vascotto and Griffith, 2006).

### Activation of Local and Distant Endogenous Stem Cells

While the *ex vivo* reconstruction of entire organs that are functional is the goal of the bioengineering world, what perhaps is even more challenging is the goal of inducing endogenous stem cells to become activated to reconstruct a tissue. Most tissues in the body display at least some sort of regenerative capability (Preston *et al.*, 2003; Tsonis, 2002) but in many cases remain insufficient to mount a spontaneous and successful repair response *in vivo*. The application or induction of growth factors and morphogens, perhaps in combination with appropriate scaffolds, might be envisioned to “encourage” local or distant progenitors to regenerate a functional tissue. This *in situ* process could occur through several different pathways, including activation of local or distant stem cells, transdifferentiation, or reprogramming, to generate adequate numbers of committed precursors. In all cases, a regulated morphogenetic process is needed to establish normal structure and function. Definition of the intrinsic properties of regenerative cells and extrinsic signals that may trigger a recapitulation of developmental processes is critical.

#### Local Cells

Based on reasoning that, following an injury, signals that normally activate a local cell to initiate repair would be either obliterated or not of a high enough magnitude, numerous studies attempted to provide appropriate morphogenetic and growth factors. However, this approach has been uniformly disappointing, most likely due to the short half-life of such soluble factors and the lack of an appropriate scaffolding. Not only does scaffolding provide a template for the organized outgrowth of local cells, but it also provides a substrate on which to stabilize and/or orient factors (or parts thereof) for appropriate presentation to a cell (reviewed in Lutolf and Hubbell, 2005; Rosso *et al.*, 2005). However, in using “smart” constructs, tissue regeneration of large defects may not be complete, due to exhaustion of the local stem cell population; hence the need to maintain a stem cell niche. Furthermore, some clues as to the negative impact of local constraints on the native, albeit incomplete, repair capacity of cells and tissues may be found in studies of spinal cord regeneration. Following injury, there is a phase characterized by neurite outgrowth from the severed end. However, it is short-lived due to the production of inhibitory factors by cells within the myelin sheath, and gliosis impedes neurite outgrowth (reviewed in Di Giovanni, 2006; Schwab, 2002). Thus, regeneration by endogenous cells must take into consideration not only the bioactive factors and scaffolding that are necessary to maintain an ingrowing population with the appropriate balance of stem cells, transiently amplifying cells, and differentiating cells, but also the inactivation of local inhibitory factors that work against the process.

### Mobilization and Recruitment of Distant Stem Cells

Numerous studies have suggested that once introduced into the circulation, many types of cells have the propensity to end up at a diseased or injured site and to participate in local regeneration (Stocum, 2001), and it has been argued that HSCs might generate a broad variety of nonhematopoietic cell types. Ongoing tissue damage and repair, at the time when systemically infused stem cells reach a target organ, may be the critical determinant for triggering their homing, engraftment, and differentiation to local cell types.

Cytokine administration has become a well-established procedure for mobilization of HSCs into peripheral blood (reviewed in Winkler and Levesque, 2006), but it is not clear that other stem cell populations present in marrow would be equally as amenable to liberation by current procedures or whether different ones would have to be developed. Consequently, mobilization of marrow stem cells might provide a mechanism to enhance a local population and improve tissue regeneration, a hypothesis that might be tested in the context of extant local, tissue-specific damage and repair.

## IV. CONCLUSIONS

The recent advances in embryonic and postnatal stem cell biology have most certainly captured the public’s attention and have raised expectations for miraculous cures in the near future. While certain applications that utilize postnatal stem cells are in practice or will be shortly, the majority are in their infancy and will take much more effort. However, the current sense of urgency in translating recent findings into clinical applications should not lead this field to repeat the mistakes experienced in the field of gene therapy. The development of tissue engineering as a viable medical practice must proceed in an evidence-based fashion in all of the associated disciplines that are involved, and several hurdles are yet to be overcome. First, our current understanding of postnatal stem cell biology is rudimentary, at best. The manner in which we isolate stem cells and manipulate them and their progeny appropriately relies heavily on a clear understanding of cell population kinetics. This also requires a complete understanding of their response not only to bioactive factors, scaffoldings, and delivery systems, but also to the host microenvironment in which they must survive and function. Second, more efficient bioreactors that adequately model the microenvironment and also allow for scale-up of the tissue-engineering process must be developed. Third, in order to translate what we learn into clinical application, development of appropriate preclinical models to prove the principle that stem cells do indeed have a positive biological impact is absolutely essential. In analyzing these models, stringent criteria must be defined to determine efficacy, and we must remain principled in assessing them. Exciting times, yes, but also a time for due diligence to bring what started off as a scientific curiosity into medical reality.

### I. INTRODUCTION

Gene transfer is a therapeutic strategy using genetic information, usually in the form of DNA, to modify the phenotype of cells. Gene therapy strategies can be useful for tissue engineering by modifying cells directly or by providing a favorable growth environment for the engineered tissue. To accomplish this, cells are modified genetically *ex vivo* or *in vivo* using gene transfer vectors that mediate the transfer of therapeutic DNA into the nucleus, where it is transcribed in parallel with genomic DNA. A variety of non-viral and viral gene therapy vectors have been developed, including plasmids, plasmids combined with liposomes, adenovirus, adeno-associated virus, retrovirus, and lentivirus. A number of strategies have evolved to enhance the targeting of gene transfer vectors by genetic or chemical modification of the surface of the vector. Gene expression directed by the transferred gene can be regulated by including inducible promoters, tissue-specific promoters, and *trans*-splicing. Although still in the early stage of development, there is significant potential to combine gene therapy with stem cell strategies to aid in controlling cell growth and to circumvent immune rejection. There are still challenges to using gene transfer for tissue engineering, but the tech-

nology of gene transfer is sufficiently advanced that rapid progress should be made in the near future.

Gene therapy uses the transfer of genetic information to modify a phenotype for therapeutic purposes (Verma and Weitzman, 2005). The application of gene transfer to tissue engineering has myriad possibilities, including the transient or permanent genetic modification of the engineered tissue to produce proteins for internal, local, or systemic use, helping to protect the engineered tissue, and providing stimuli for the engineered tissue to grow and/or differentiate. To provide a background for the application of gene transfer to tissue engineering, this chapter reviews the general strategies of gene therapy, details the gene transfer vectors used to achieve these goals, and discusses the strategies being used to improve gene transfer by modifying the vectors to provide cell-specific targeting and by regulating the expression of the targeted gene. The applications combining gene therapy with stem cell therapy are reviewed. Our overall goal is to provide a state-of-the-art review of the technology of gene therapy, including the challenges to making gene therapy for tissue engineering a reality. For details regarding the applications of gene therapy to specific organs and clinical disorders, several reviews are avail-

able (Anderson, 1998; Crystal, 1995; Kaji and Leiden, 2001; Lundstrom, 2003; O'Connor and Crystal, 2006; Thomas *et al.*, 2003; Verma and Weitzman, 2005).

## II. STRATEGIES OF GENE THERAPY

The basic concept of gene therapy is to transfer nucleic acid, usually in the form of DNA (or RNA in retrovirus and lentivirus vectors), to target cells. The vector, with its gene cargo, can be administered *ex vivo*, where the gene is transferred to the cells of interest in the laboratory and the genetically modified cells restored to the patient, or *in vivo*, when the nucleic acid is administered directly to the individual (Fig. 34.1). Independent of the overall strategy, an expression cassette containing the genetic sequences to be delivered, typically a cDNA along with regulatory sequences to control expression, is inserted into a “vector,” a nonviral or viral package used to improve efficiency and specificity of the gene transfer. Together, the choice of vector, the design of the expression cassette, and the coding sequences of the gene determine the pharmacokinetics of the resulting gene expression.

Simple in concept, gene transfer is complex in execution. In addition to choosing an *ex vivo* vs. *in vivo* strategy, the major issues relating to successful gene therapy are the design of vector, how the vector is delivered to the cell population of interest, translocating the vector/expression cassette from outside the cell to the nucleus, and the expression of the gene to obtain the desired therapeutic effect (Fig. 34.2). Independent of the choice and design of the gene transfer vector, successful gene therapy requires decisions regarding the quantity of vector required to modify the numbers of target cells necessary to obtain the desired therapeutic effect and whether or not the vector will evoke a host immune response and/or cause unacceptable toxicity. The

gene therapist must also decide how to get the vector to the target cells, including targeting specificity and avidity of the vector for its relevant receptor. Once the vector reaches the cells of interest, the gene cargo within the vector must be translocated from outside of the cell to within the nucleus. In designing the gene transfer strategy, it is critical to decide whether or not the gene is to be inserted into the chromosomal DNA of the target cells. Finally, the transferred gene must be expressed, with the concomitant issues of amount and control of expression and host immunity and toxicity that may be evoked by the expression of the gene. In the sections that follow, we discuss all of these issues.

## III. EX VIVO VS. IN VIVO GENE THERAPY

There are generally two strategies by which gene therapy technology can be used for genetic engineering: *ex vivo* transfer of genetic material, with subsequent transfer of the modified cells or tissue to the host, and *in vivo* transfer, with direct administration of the gene therapy vectors to the patient (Fig. 34.1).

### Ex Vivo

The *ex vivo* strategy has the advantage that the cell population can be purified and carefully defined, and the transfer of the gene is limited to that cell population and not to other cells or tissues. The challenge for this approach is that, for most applications, once returned to the patient, the genetically modified cells need to have a selective advantage to modulate the therapeutic goal. For applications where long-term expression of the gene is required and the transferred cells subsequently replicate within the patient, the vectors used to transfer the gene must mediate integration of the gene so that it persists when the cell divides (Verma and Weitzman, 2005).

**FIG. 34.1.** General strategies for gene therapy for tissue engineering. **(A)** *Ex vivo* strategies use a gene transfer vector to genetically modify autologous target cells (e.g., skin fibroblasts) *in vitro*, followed by transfer of the genetically modified cells back to the patient. **(B)** *In vivo* strategies transfer the therapeutic gene by direct administration of a gene transfer vector to the patient.

**FIG. 34.2.** Issues relating to successful gene transfer. In addition to the choice of vector, successful gene transfer requires decisions regarding the quantity of vector to be used and that the vector does not induce immunity and/or toxicity that will limit its use. The vector has to be transferred to the cell, a relatively easy task for *ex vivo* strategies, but *in vivo* may require enhancing targeting specificity and vector avidity to its receptor. Once reaching the target cells, the vector must ensure its gene cargo is efficiently translocated to the nucleus. In the nucleus, the gene must be expressed in appropriate amounts, with control if necessary and without appreciable immunity and/or toxicity induced by the gene product.

The *ex vivo* strategy typically is used to genetically modify hematopoietic cells, such as CD34+ cells derived from bone marrow, or skin fibroblasts (Kaji and Leiden, 2001). Examples of *ex vivo* gene transfer strategies include the correction of hereditary immunodeficiencies with retroviral vectors, transfer of the factor VIII gene to autologous fibroblasts to treat hemophilia A, and transfer of suicide genes to T cells to control graft vs. host disease (Cavazzana-Calvo *et al.*, 2005; Qasim *et al.*, 2005; Roth *et al.*, 2001). For tissue-engineering applications, the *ex vivo* strategy is applicable to providing genes to enhance and/or modulate the growth of the engineered tissue as well as to protect the engineered tissue from host responses or disease processes. The *ex vivo* strategy is also the most suitable strategy to use gene transfer to genetically modify stem cells.

Although *ex vivo* gene therapy can be carried out using cells derived from a nonautologous source, potential immune rejection of nonmatched cells generally requires that autologous, or closely matched donor, cells be used for the tissue-engineering strategy. However, the immune system can potentially recognize components of the vector and/or transferred gene product. For *ex vivo* strategies in general, immune recognition of the gene therapy vector is minimal, because the immune system will be in contact not with the total dose of gene therapy vector used to transfer

the gene *in vitro*, but only the residue of the vector within the cells to be transferred. There is the possibility of immune recognition via MHC presentation of viral antigens inducing antivector immunity, and this may be responsible for the shutdown of gene expression over time.

### In Vivo

*In vivo* gene transfer strategies administer the gene therapy vector either directly to the target organ or via the vascular system into vessels feeding that organ. *In vivo* gene transfer has an advantage over *ex vivo* strategies in that it avoids the cumbersome (and costly) process of removing cells from the patient, manipulating the cells *in vitro*, and returning the genetically modified cells to the patient. Challenges that need to be overcome for *in vivo* gene transfer strategies include the induction of immunity by the gene transfer vector, transport of the gene therapy vector to the targeted cells/organ, efficient binding of the vector to the cell, translocation of the genetic material to the nucleus, and toxicity and immunity induced by expression of virus and/or transgene peptides.

## IV. CHROMOSOMAL VS. EXTRACHROMOSOMAL PLACEMENT OF THE TRANSFERRED GENE

One of the critical decisions in strategizing gene therapy is whether the transferred gene is to be inserted into the chromosomal DNA of the targeted cells or is designed to function in an extrachromosomal location within the nucleus. There are advantages and disadvantages to both strategies, and the choice of the strategy is determined by the specific application of the gene transfer.

As described later, some gene transfer vectors (e.g., retrovirus, lentivirus) insert their genome, and hence the transferred gene, directly into the chromosomal DNA of the target cells. This has the advantage that it is permanent; and when the genetically modified cells divide, both daughter cells have the newly transferred sequences, for they are now part of the genome of the genetically modified cell population. This is a desirable feature for applications where persistent gene expression is required, such as for the correction of a hereditary disorder. The disadvantage is that, once inserted, the gene cannot be removed, and thus unless controls are designed into the transferred sequences, cannot be shut down. Equally important is the issue of randomness of where the gene is inserted. If the gene is inserted into a relatively "silent" region of the genome, the resulting gene expression will be low, while gene expression from other regions will be high (Bushman *et al.*, 2005). This genome regional modulation of the level of gene expression will be different for each targeted cell. While there are some more favored regions of gene insertion, depending on the vector characteristics, the population of genetically modified cells essentially becomes a mixed population in terms of where

the gene has been inserted. Thus, expression may be low for some cells, while other cells may be average or high expressors. More troubling is that if the gene is inserted into a region influencing cell proliferation, the result may be uncontrolled cell growth, e.g., malignancy. This phenomenon, referred to as *insertional mutagenesis*, has been observed in experimental animal and human applications of gene transfer (Bushman *et al.*, 2005).

Some vectors (e.g., nonviral, adenovirus, adeno-associated virus) transfer the gene into the nucleus, but mostly into an extrachromosomal location, where the gene is transcribed using the same transcriptional machinery as for genomic DNA (Verma and Weitzman, 2005). The consequences of this strategy is that as long as the cells do not proliferate and as long as host defenses do not recognize the genetically modified cell as foreign, expression of the transferred gene will persist. However, if the cell divides, the transferred gene will not be replicated, and gene expression in the daughter cells will eventually wane as proliferation continues. The consequences are transient expression of the gene, a “pharmacokinetic” result that is ideal for some applications (e.g., angiogenesis, most cancer therapies) but not desirable for applications requiring persistent expression (e.g., correction of a genetic disease). Independent of the issue of persistence of gene expression, extrachromosomal placement of the gene has the advantage that insertional mutagenesis and variability of gene expression secondary to variability of chromosomal insertion are of no concern.

## V. GENE TRANSFER VECTORS

There are two general classes of commonly used vectors for gene therapy: nonviral and viral (Fig. 34.3, Table 34.1). Although a variety of vectors have been developed in both classes, the most commonly used nonviral vectors are naked plasmids and plasmids combined with liposomes, and the commonly used viral vectors are adenovirus, adeno-associated virus, retrovirus, and lentivirus (Lundstrom, 2003; Thomas *et al.*, 2003; Verma and Weitzman, 2005).

Independent of the vector used, all carry an expression cassette, which includes the gene to be transferred together with the relevant regulatory sequences to control the expression of the gene once it has been transferred to the target cells (Fig. 34.3A). The typical expression cassette includes (5' to 3') a promoter, an intron (this is not critical, but it usually enhances gene expression and enables specific PCR identification of the cytoplasmic mature mRNA from the pre-mRNA and transferred expression cassette), the transgene itself (usually in the form of a cDNA, but it can contain one or more introns or can be the generic form of the gene), and finally the polyA/stop and other 3' regulatory sequences, if desired. In special cases, such as *trans*-splicing (discussed in the section on regulation of expression), the expression cassette may contain only a fragment of the gene together

with sequences to direct splicing into an endogenous nuclear pre-mRNA.

### Nonviral Vectors

The most simple gene transfer vectors are plasmids. To achieve relevant transduction of cells *in vivo*, the plasmids are usually combined with liposomes to facilitate attachment and entry into target cells (Lechardeur *et al.*, 2005; Miller, 1999). A variety of physical methods have also been developed to promote entry of plasmids into target cells, including microinjection, hydrodynamic administration, electroporation, ultrasound, and ballistic delivery (the so-called “gene gun”) (Miller, 1999). Most of these physical methods of gene delivery are not applicable for *in vivo* gene transfer due to the inaccessibility of the target cells to direct manipulation.

Plasmids contain a relatively simple expression cassette, with the transgene driven by a promoter and flanked by an intron and the polyadenylation/stop site (Fig. 34.3A). Plasmid DNA has an unlimited size capacity; however, because plasmids larger than 10 kb are potentially unstable, during production most gene transfer strategies being considered for human applications use plasmids under 10 kb. Although plasmids can efficiently transduce cells *in vitro*, their efficiency *in vivo* is limited. There have been many attempts to correct hereditary disorders with plasmid gene transfer alone, but with little evidence of expression of the plasmid-directed mRNA in those trials (Montier *et al.*, 2004). Part of the reason for the inefficiency of plasmid-mediated gene transfer is that plasmids have no means to direct their traffic to the nucleus (Lechardeur *et al.*, 2005). For gene transfer applications for tissue engineering, the most that can be envisioned for the use of plasmid-based systems is to use them in an *ex vivo* approach, with the possible need for selection of the transduced cells.

### Adenovirus

Adenoviruses are nonenveloped viruses containing a linear double-stranded DNA genome of 36 kb (Shenk, 2001). Among the 49 different Ad strains that infect humans, serotype 5 and serotype 2 of subgroup C are widely used in gene transfer studies and are the only serotypes used in humans to date. The Ad5 genome is composed of early and late genes (Shenk, 2001). The E1 region controls the replication of the virus. Conventionally, the Ad gene transfer vectors have a deletion in E1 and E3 (a nonessential region). The expression cassette containing the promoter and the gene to be transferred are usually inserted into the E1 region. The vectors are produced in the 293 embryonic kidney cell line that provides the E1 information in *trans*, enabling replication of the recombinant vector.

Ad vectors can hold 7–7.5 kb of exogenous sequences (Shenk, 2001). If more space is needed, the E2 or E4 region can also be deleted and the vector made in cell lines providing these deleted sequences. The Ad capsid is an icosahedron.

The plasmid genome can be unlimited in size, but usually the expression cassette is under 10 kb; the liposome/plasmid combination ranges from 50 to 200 nm in diameter. **(C)** Commonly used viral vectors, including adenovirus, adeno-associate virus, lentivirus, and retrovirus. Shown is the size of the genome of each viral vector as well as the relative size of each vector. The size of the expression cassette depends on how much of the viral genome is included.

dral structure composed of 252 subunits, of which 240 are hexons and 12 are pentons. Hexon is the major structural component of the Ad capsid, forming 20 facets of the icosahedron, and is composed of three tightly associated molecules of polypeptide II forming a trimer. Polypeptide IX is associated with the hexon protein and serves to stabilize the structure. Each penton contains a base and a noncovalently projecting fiber. Sequences within the fiber are the primary means by which Ad interact with cells, with the penton base providing secondary attachment sequences.

Several cellular receptors have been identified for Ad vectors, and they differ for various serotypes (Table 34.2). The primary Ad receptor for the subgroup C Ad is the coxsackie adenovirus receptor (CAR) (Bergelson *et al.*, 1997). CAR is expressed on most cell types, and thus Ad group C vectors are capable of transferring genes to most organs. Besides the primary CAR receptor, epitopes in the penton base of the group C Ad vectors use  $\alpha_v\beta_3$  (or  $\alpha_v\beta_5$ ) surface integrins as coreceptors for virus internalization (Wickham *et al.*, 1993). Heparan sulfate has also been identified as a

**Table 34.1.** Characteristics of most commonly used gene transfer vectors

<i>Vector type</i>	<i>Maximum expression cassette capacity (kb)</i>	<i>Transfers genes to nondividing cells</i>	<i>Antivector immunogenicity</i>	<i>Chromosomal integration</i>	<i>Expression</i>	<i>Other characteristics</i>
Plasmids/ liposomes	<10 <sup>1</sup>	Yes	None	No	Transient	Poor transduction efficiency
Adenovirus	7–8 <sup>2</sup>	Yes	High	No	Transient	Typically, mediates expression for 1–3 wk
Adeno-associated virus	4.5	Yes	Low	No <sup>3</sup>	Persistent in nondividing cell populations	Expression usually takes 1–3 wk to be initiated
Retrovirus	8	No	None	Yes	Persistent	Risk for insertional mutagenesis; difficult to produce in high titer
Lentivirus	8	Yes	None	Yes	Persistent	Theoretical safety concerns regarding HIV components; risk for insertional mutagenesis; difficult to produce in high titer

<sup>1</sup>Plasmid size is generally not limited, but plasmids with >10-kb expression cassette capacity are more difficult to produce with consistent fidelity and thus are generally not suitable for gene human transfer.

<sup>2</sup>Typically, Ad vectors have a 7 to 8 kb capacity for the expression cassette; the capacity can be increased by removing additional viral genes.

<sup>3</sup>Wild-type adeno-associated virus (AAV) integrates in a site-specific fashion into chromosome 19, a process mediated by the *rev* gene; *rev* is deleted in the AAV gene transfer vectors; whether or not there is minimal integration of the genome AAV gene transfer vectors is debated (McCarty *et al.*, 2004; Qing *et al.*, 1999; Summerford *et al.*, 1999; Summerford and Samulski, 1998).

receptor for Ad2 and Ad5, and Ad5 has been shown to bind to vascular cell adhesion molecule 1 (VCAM 1) on endothelial cells and possibly also to MHC class I on the cell surface (Chu *et al.*, 2001; Hong *et al.*, 1997).

The group B serotypes Ad 11, 14, 16, 21, 35, and 50 utilize CD46 instead of CAR, enabling more efficient gene transfer into hematopoietic cells, cells of the urinary tract epithelium, and salivary glands (Sirena *et al.*, 2004). For Ad3 of the subgroup B Ad vectors, CD80 and CD86, which are usually expressed on antigen-presenting cells, have been identified as receptors for viral entry (Short *et al.*, 2006).

In addition to Ad vectors being effective in delivering genes to a wide variety of cell types for therapeutic purposes, Ad vectors interact rapidly with antigen-presenting cells such as dendritic cells, leading to the induction of immunity against the vector and potentially also against the transgene if it is foreign to the host (Hackett *et al.*, 2000; Thomas *et al.*, 2003). When Ad are administered directly in large doses to animals and humans, there is an innate and acquired immune response against the vector, resulting in local inflammation and infiltration of CD4, CD8, and dendritic cells (Hackett *et al.*, 2000). The immune response is

multifaceted, consisting of humoral and cellular immunity against both the capsid proteins and the transgene expressed by the vector if it is foreign to the host.

Several strategies have been investigated to circumvent the problem of host responses evoked against Ad gene transfer vectors, including the use of immunosuppressants administered together with the vector or including transgenes expressing immunomodulatory factors to suppress the immune responses against the vector (Hackett *et al.*, 2000). Considerable effort has also been placed on circumventing the host response by designing vectors with larger genomic deletions (e.g., of E1 plus E2 and/or E4 with complementing cell lines) that evoke a milder immune reaction (Hackett *et al.*, 2000; Lundstrom, 2003).

One challenge to the use of Ad vectors is preexisting immunity against the vector resulting from previous infection with a wild-type Ad virus from the same serotype (Hackett *et al.*, 2000). The acquired host responses to Ad

vector administration generally result in the inability to readminister a vector of the same serotype. To circumvent this problem, alternative serotypes can be administered, thus circumventing immunity against the first vector (Mastrangeli *et al.*, 1996). Also, different serotypes to which humans are usually not exposed have been developed as gene transfer vectors. One example is Ad serotype 48, to which humans rarely have preexisting immunity. A chimeric Ad vector containing the hexon loops of Ad5 replaced by those of Ad48 have been shown to be a possible strategy for an Ad-based genetic vaccine approach (Roberts *et al.*, 2006) and could also be envisioned to be useful for tissue-engineering applications.

Another strategy to circumvent preexisting anti-Ad immunity is the use of nonhuman Ad serotypes (Basnight *et al.*, 1971; Farina *et al.*, 2001; Hashimoto *et al.*, 2005). Non-human primate-derived Ad vectors were developed to overcome preexisting immunity to common human Ad serotypes

and to broaden the repertoire of Ad when used as vaccines. For example, Ad vectors based on nonhuman primate serotypes C68, C6, and C7 do not circulate in the human population and are therefore not affected by preexisting immunity (Basnight *et al.*, 1971; Farina *et al.*, 2001; Hashimoto *et al.*, 2005).

### Adeno-Associated Virus (AAV)

AAV is a single-stranded DNA virus that belongs to the *Dependovirus* genus of the Parvoviridae family. AAVs were originally isolated as contaminants in laboratory stocks of adenoviruses (Muyzyczka and Berns, 2001). Over recent decades, six different isolates of AAV were characterized, most derived from laboratory stocks of adenoviruses and one isolated from a condylomatous wart. Nine subtypes of AAV have been described for which humans are the primary host (Muyzyczka and Berns, 2001). These isolates were found to be different, based on the antibody response generated against them, and were thus categorized as AAV serotypes 1–9. A substantial portion of humans have detectable antibodies against these serotypes. The exact nature and sequelae of the natural infection with AAV in humans are not known, and there is possibly no human disease associated with AAV.

AAV consists of a single-stranded 4.7-kb genome with characteristic termini of palindromic repeats that fold into a hairpin shape known as *inverted terminal repeats* (ITR) (Muyzyczka and Berns, 2001). During replication into a double-stranded form it expresses genes involved in replication (*rep*) and genes that code for the capsid proteins (*cap*). In the absence of a helper virus such as adenovirus or herpes simplex, wild-type AAV is capable of infecting non-dividing cells and integrating its genome into chromosomal DNA at a specific region on chromosome 19, persisting in a latent form. In the gene vectors, *rep* and *cap* are deleted, and most of the vector genome resides and functions in an extrachromosomal location (Muyzyczka and Berns, 2001).

In the AAV vectors, the *rep* and *cap* genes are replaced with an expression cassette. During vector production, the *rep* and *cap* gene products as well as the necessary helper-virus elements (usually Ad-derived) are supplied *in trans*. AAV vectors are commonly produced by transfecting two plasmids into the 293 human embryonic kidney packaging cell line. DNA coding for the therapeutic gene is provided by one plasmid, and the AAV *rep* and *cap* functions plus the Ad helper functions are provided by the second plasmid. Titers are generally significantly lower than those obtained for Ad vectors, but they are sufficient to produce enough vectors for clinical trials.

Numerous studies in animals have been performed to assess the safety and efficacy of AAV-based vectors, and AAV2 serotype-based vectors have been assessed in humans (Carter, 2005). AAV vectors are capable of transducing non-dividing cells *in vitro* and *in vivo*. The exact molecular intracellular state of the vector genome has not been completely

elucidated, but there is little evidence that the vectors integrate when used in gene therapy *in vivo*. Most transgene expression is thought to be derived from extrachromosomal viral genomes that persist as double-stranded circular or linear episomes (Nakai *et al.*, 2000). This limits the usefulness of AAV for applications involving dividing cells, such as stem cells, since only one daughter cell will receive the vector genome (Nakai *et al.*, 2001).

One disadvantage of AAV vectors is their packaging capacity, limited to expression cassettes of about 4.5 kb. This size limitation is a challenge for the use of AAV vectors for clinically relevant large transgenes, such as dystrophin (11 kb) for muscular dystrophy or factor VIII (7–9 kb) for hemophilia A. Various efforts have been undertaken to deliver larger transgenes using AAV vectors, including co-administration of two vectors, each carrying one-half of the transgene, leading to intermolecular recombination during concatamerization, an intermediate state of the vector genome. *Trans*-splicing may also be employed as a strategy to circumvent the need to package the full-length cDNA into the AAV vector. Instead, delivering the full coding sequences, the gene is split into two pieces that then combine at the pre-mRNA level (Pergolizzi and Crystal, 2004).

The host immune response against AAV vectors is not as strong as that observed with Ad vectors (Hackett *et al.*, 2000; Jooss and Chirmule, 2003). AAV vectors generate humoral immunity against the capsid proteins, which impairs readministration of a vector of the identical serotype. Cellular immunity against AAV has been detected following administration to experimental animals and humans. But, unless high doses are used, there usually are no destructive cytotoxic T-cell responses generated against the vector or the transgene (Jooss and Chirmule, 2003).

There is usually persistent expression of the transgene directed by AAV vectors, particularly in organs with nondividing (or slowly dividing) cells, such as liver, muscle, heart, retina, and brain. The overall expression levels of the transgene appear to be lower with AAV than with Ad and are dependent on the target organ. Recently, novel AAVs have been identified from tissues of nonhuman primates and humans (Gao *et al.*, 2004, 2002). These AAVs have substantial heterogeneity in the capsid genes and are useful as chimeric capsids combined with the AAV2 genome, leading to improved infection of organs or tissues previously not considered to be valuable targets for AAV gene transfer.

AAV interacts with its target cells by binding to cell surface receptors (Table 34.2). For AAV2, the primary attachment receptor is heparan sulfate proteoglycan (Summerford and Samulski, 1998). AAV3 may share heparan sulfate proteoglycan as the primary attachment receptor. However, AAV3 may use other receptors, for AAV3 has been shown to infect hematopoietic cells, which were not effectively infected by AAV2 (Handa *et al.*, 2000). AAV4 and AAV5 use sialic acid as the primary attachment receptor. AAV4 uses O-linked sialic acid, whereas AAV5 uses N-linked sialic

acid (Kaludov *et al.*, 2001; Walters *et al.*, 2001). For serotypes AAV1 and AAV6, no receptors have been identified (Halbert *et al.*, 2001), nor have the receptors for the nonhuman primate AAVs (Gao *et al.*, 2002).

AAV2 also uses coreceptors for efficient infection, including  $\alpha_v\beta_5$  integrin (Summerford *et al.*, 1999) and fibroblast growth factor-1 (Qing *et al.*, 1999). Efficient infection with AAV5 appears to require a coreceptor; platelet-derived growth factor has been identified as a possible coreceptor for AAV5 but may also be able to act as the primary receptor (Di *et al.*, 2003).

## Retrovirus

Retrovirus and lentivirus vectors are both RNA-based vectors belonging to the family of retroviridae. Because lentiviruses are capable of infecting nondividing cells, they are discussed separately herein. The original retroviral vectors used for gene therapy were based on endogenous murine viruses. Of these, the Moloney murine leukemia retrovirus (MMLV) was the first widely used gene transfer vector and was the first to be used to treat a hereditary disorder using an *ex vivo* strategy (Blaese *et al.*, 1995).

The genome of the retrovirus vector is a 7- to 10-kb single-stranded RNA containing long terminal repeats (LTRs) on both ends that flank *rev*, *gag*, *pol*, and other regulatory genes that are required for viral function. The RNA genome of the replication-deficient retroviral vectors contain an expression cassette up to 8 kb that replaces all viral protein-coding sequences. The LTRs flank the expression cassette and allow transcription initiation by host cell factors. The vectors are rendered self-inactivating by deletion of the promoter and enhancer in the 3' LTR, to prevent LTR-driven transcription. The packaging of the genomic RNA is controlled in *cis* by the packaging signal  $\Psi$ . The production of the retrovirus vectors requires a packaging or producer cell line in which the viral *gag*, *pol*, and *env* proteins are expressed in *trans* from separate helper products. Recombination between the helper constructs and the vector can be minimized by using nonretroviral regulatory sequences to control expression (Cosset *et al.*, 1995). Enhancer and promoter sequences can be deleted from the 3' LTR to create a transcriptionally silent 5' LTR during infection of the target cells. This strategy provides the basis for self-inactivating vectors and can also be used for the substitution with tissue-specific promoters (Yu *et al.*, 1986). The main reason why MMLV viruses can infect only nondividing cells is that they are unable to cross the nuclear membrane and can only achieve completion of the infection with provirus integration during cell division.

Retroviruses enter the cells via cell fusion of the envelope protein with the cell membrane. The murine viruses are able to infect only murine cells (ecotropic), whereas derivatives of MMLV or human retroviruses, such as vesicular stomatitis virus (VSV), can infect both human and murine cells (amphotropic; Table 34.2). Providing the virus

with a different coat, a process referred to as *pseudotyping*, can change the specificity of binding and entry into target cells. Over the past decade, there has been considerable effort in the development of pseudotyping strategies of retroviral vectors (Cosset *et al.*, 1995; Markowitz *et al.*, 1988; Miller *et al.*, 1991).

Most of the gene transfer strategies for retroviral vectors have been *ex vivo* approaches, due to the difficulty in producing high-titer concentrated preparations and the rapid inactivation of the retroviral vectors *in vivo* by complement. Due to their ability to infect rapidly dividing cells, retroviral vectors have been used extensively to develop gene transfer strategies to hematopoietic cells. The first clinical trial to treat a hereditary disorder used a retrovirus to transduce T-cells of patients with adenosine deaminase — severe combined immunodeficiency (SCID) (Blaese *et al.*, 1995).

One advantage of using retroviral vectors is the permanent integration of the vector genome into the host genome, providing long-term and stable expression of the transgene. This, however, also carries the greatest risk of retroviral vectors, in that they may induce insertional mutagenesis, with the subsequent development of malignancies. This has been observed in a clinical trial using an MMLV-based retroviral vector to correct hematopoietic stem cells to treat X-linked SCID (Cavazzana-Calvo *et al.*, 2005). Although long-term correction of the immunodeficiency has been observed in the study subjects, three children developed a clonal lymphoproliferative syndrome similar to acute lymphoblastic leukemia. In two of these cases, there was integration of the retroviral vector near the LIM-domain-only-2 (LMO2) promoter.

## Lentivirus

Based on the knowledge that the human retrovirus HIV-1 is able to infect nondividing cells such as macrophages and neurons, replication-defective versions of HIV were developed that were capable of infecting nondividing cells and achieving stable long-term expression through integration of the provirus into chromosomal DNA (Buchsacher and Wong-Staal, 2000). The genome of a lentivirus vector is a 9- to 10-kb single-stranded RNA genome, containing components of HIV-1 but otherwise similar to that of retroviral vectors. All viral protein-coding sequences are deleted and are replaced with an expression cassette that can be up to 8 kb.

Unique to lentiviruses are the central polypurine tract (cPPT) and central termination sequences (CTS), *cis*-acting sequences that coordinate the formation of a central DNA flap, which improves nuclear import (Sirven *et al.*, 2000). This may explain the increased transduction efficiency of lentiviral as compared to retroviral vectors. A *rev*-responsive element can be incorporated into the vector to facilitate the nuclear export of unspliced RNA. The packaging of the genomic RNA is controlled in *cis* by the packaging signal  $\Theta$ .

Despite the greater complexity of the lentivirus genome, the basic principles of generating vectors free of a replication-competent virus are similar to those for retroviral vectors. Packaging systems use the HIV *gag* and *pol* genes, with or without the *rev* gene (Klages *et al.*, 2000; Kotsopoulou *et al.*, 2000). The HIV virulence genes *tat*, *vif*, *vpr*, *vpu*, and *nef* are completely absent from lentiviral vectors, thus making it theoretically impossible that a virus similar to HIV can be inadvertently produced (Kim *et al.*, 1998). The production of lentiviral vectors in high concentrated titers is still a challenge, but the production issues are slowly being solved (Buchschacher and Wong-Staal, 2000).

The cellular receptors for the lentivirus vectors are the same as for HIV1-1, including CD4, together with the chemokine coreceptors CCR5 and CXCR4 (Table 34.2). However, the lentiviral gene transfer vectors are usually pseudotyped with envelopes from other viruses, such as VSV-G, mediating the binding and entry into target cells similar to retroviral vectors. Efficient gene transfer of lentiviral vectors has been reported for a variety of dividing and nondividing cell types, including muscle, neurons, glia, and hematopoietic cells. Lentivirus vectors have been used successfully to correct disease phenotypes in experimental animals for CNS disorders such as metachromatic leukodystrophy using *in vivo* administration of the lentiviral vector to the brain (Consiglio *et al.*, 2001) or, using an *ex vivo* strategy, by infecting hematopoietic stem cells with the  $\beta$ -globin gene to correct  $\beta$ -thalassemia (Sadelain *et al.*, 2005).

Like retroviral vectors, insertional mutagenesis is a concern for the clinical use of lentiviral vectors, and liver cancers have been observed in mice infected *in utero* or neonatally with lentiviral vectors (Themis *et al.*, 2005). One hypothesis for this phenomenon is based on potentially oncogenic sequences present in the woodchuck hepatitis virus–derived posttranscriptional regulatory element (WPRE) that was included in the vector to increase mRNA stability (Themis *et al.*, 2005). The only clinical trial using lentiviral vectors that has been initiated is in patients infected with HIV receiving *ex vivo* lentivirus-modified autologous CD4 T-cells to treat the HIV-1 infection (MacGregor, 2001).

## VI. CELL-SPECIFIC TARGETING STRATEGIES

Viral gene transfer vectors use the receptors of their wild-type versions to enter into cells (Table 34.2). Modification of gene transfer vectors to target specific cell types or tissues is an attractive means to increase the specificity of the vectors to the target cell and may also enable the vectors to infect cells that are usually not infected by unmodified vectors. In general, targeting modifications can be accomplished either by genetic modification of the vector genome to change the properties of the outer surface of the vector or by chemical modification of the vectors via the addition of ligands (Table 34.3). Based on the targeting strategy used, the range of tropism can be widened or narrowed (Fig. 34.4).

## Targeting of Ad Vectors

Strategies have been developed to redirect Ad tropism and to enhance Ad tropism for cells difficult to transfer genes to because of lack of Ad receptors. In general, Ad vectors exhibit a broad tropism due to the widespread expression of the primary Ad receptor CAR and the secondary integrin receptors  $\alpha_v\beta_3$  and  $\alpha_v\beta_5$ . While the widespread expression of the Ad receptors enables the efficient infection of a wide range of target cells, it poses the problem of unwanted uptake and gene expression in nontarget tissue when the vectors are administered *in vivo*. Some tissues have low expression of CAR (e.g., endothelial cells, antigen-presenting cells, and some tumor cells), which limits the use of Ad vectors for these targets.

Most genetic targeting strategies for Ad vectors have been focused on ablating CAR binding and have introduced new peptides or other ligands to the fiber knob domain, the primary site for the interaction of group C Ad vectors with CAR (Nicklin *et al.*, 2005). Fiber modifications to modify target–cell binding of Ad vectors include the introduction of poly(L) lysine to allow binding to heparan-containing receptors and the integrin-binding motif RGD, which is essential for penton-mediated internalization to allow integrin-mediated binding and uptake (Wickham *et al.*, 1997). Peptides can also be incorporated into other sites of the Ad capsid to achieve retargeting, such as incorporation of RGD into the hexon (Vigne *et al.*, 1999) and poly(L) lysine into polypeptide IX (Dmitriev *et al.*, 2002).

Another approach of genetic retargeting of virus vectors is to create chimeras of different serotypes, which are known to use different cellular receptors. Replacing the fiber or fiber knob domain of the Ad5-based vector with that of Ad3 or Ad7 has been shown to achieve CAR-independent infectivity (Gall *et al.*, 1996; Krasnykh *et al.*, 1996; Stevenson *et al.*, 1995). Replacement of the fiber of Ad2 with that of Ad17 has led to improved infectivity of airway epithelial cells (Zabner *et al.*, 1999). Replacement with the fiber of Ad35 achieved improved infectivity of hematopoietic cells (Saban *et al.*, 2005; Shayakhmetov *et al.*, 2002), and Ad16 enhanced infectivity of cardiovascular tissue (Havenga *et al.*, 2001). Ad5 vectors pseudotyped with fibers of the subgroup D Ad 19 and 37 increased the infectivity of endothelial and smooth muscle cells (Denby *et al.*, 2004). Recognition peptides for fiber modification have been identified by phage display (Nicklin *et al.*, 2000; Pereboev *et al.*, 2001; Xia *et al.*, 2000), and other complex genetic modifications of the fiber to retarget the Ad vector have been reported (Hong *et al.*, 2003; Krasnykh *et al.*, 2001). These cell-targeting modifications can also be combined with the use of tissue-specific promoters to achieve selective infection and transcription in the targeted cell type. For example, inserting the RGD motif into the fiber has been combined with the use of the endothelial cell-specific Flt-1 promoter and resulted in more specific infection and gene expression in endothelial cells

**Table 34.3.** Alteration of viral gene transfer vector cell targeting by modifying capsid/envelope structure

<i>Modification</i>	<i>Viral vector</i>	<i>Examples</i>	<i>Purpose/target</i>	<i>References</i>
Genetic alteration of capsid/envelope proteins	Adenovirus	Delete CAR <sup>1</sup>	CAR-independent infection	Kirby <i>et al.</i> (1999)
		Add RGD <sup>2</sup> to fiber	$\alpha_v\beta_3$ , $\alpha_v\beta_5$ integrins	Wickham <i>et al.</i> (1997)
		Add polylysine to fiber or protein IX	Broadening infectivity by targeting heparan-containing molecules	Dmitriev <i>et al.</i> (2002); Wickham <i>et al.</i> (1997)
		Replace Ad5 fiber with Ad19 or Ad37 fiber	Improved infection of smooth muscle and endothelial cells	Denby <i>et al.</i> (2004)
		Replace Ad5 fiber with Ad37 fiber	Infection of hematopoietic cells	Shayakhmetov <i>et al.</i> (2000)
		Replace Ad5 fiber knob with Ad3 fiber knob	CAR-independent infection	Krasnykh <i>et al.</i> (1996); Stevenson <i>et al.</i> (1997)
		Replace Ad5 fiber with Ad7 fiber	CAR-independent infection	Gall <i>et al.</i> (1996)
		Replace Ad2 fiber with Ad17 fiber	Improved infection of airway epithelial cells	Zabner <i>et al.</i> (1999)
		Replace Ad5 fiber with Ad16 fiber	Improved infection of smooth muscle and endothelia cells	Havenga <i>et al.</i> (2001)
		Replace Ad5 fiber with trimerization motif of phage T4 fibrin	Chimeric fiber phage fibrin molecules targeted to artificial receptors	Krasnykh <i>et al.</i> (2001)
		Replace Ad5 fiber knob with CAV2 <sup>3</sup> fiber knob	Target to CAR-deficient cells	Glasgow <i>et al.</i> (2004)
		Replace Ad5 fiber with fiber of ovine AdV7	Targeting to kidney and “detargeting” of CAR	Nakayama <i>et al.</i> (2006)
		Add VSV <sup>4</sup> -G epitope to Ad5 fiber knob	Targeting tropism to CAR-deficient cell expressing phosphatidylserine	Yun <i>et al.</i> (2003)
		Replace 7 hypervariable regions (HVR) of Ad5 hexon with HVR of Ad48	Circumvention of anti-Ad5 hexon immunity for Ad-based HIV vaccine	Roberts <i>et al.</i> (2006)
		Adeno-associated virus	Pseudotyping entire capsid with different serotype	Targeting tropism based on capsid serotype
	Pseudotyping with capsid of multiple serotypes		Generate mosaic AAV to target different serotype tropisms	Bowles <i>et al.</i> (2003); Hauck <i>et al.</i> (2003)
	Addition of L14 <sup>5</sup> to AAV2 capsid		Targeting to L14-binding integrins	Girod <i>et al.</i> (1999)
	Incorporation of tumor-targeting peptide to AAV2 capsid		Targeting to CD13	Grifman <i>et al.</i> (2001)
	Insertion of serpin receptor ligand to AAV2 capsid		Targeting to serpin receptor	Wu <i>et al.</i> (2000)
			Ad5 capsid with Ad37 fiber and partial AAV genome	Vector with increased capacity and tropism for hematopoietic cells

**Table 34.3.** Alteration of viral gene transfer vector cell targeting by modifying capsid/envelope structure—cont'd

<i>Modification</i>	<i>Viral vector</i>	<i>Examples</i>	<i>Purpose/target</i>	<i>References</i>
Chimerical modifications of capsid/envelope	Retrovirus	Pseudotyping entire envelope with envelope of vesicular stomatitis virus, Gibbon ape leukemia virus, murine leukemia virus	Targeting tropism of new envelope (from ecotropic to amphotropic)	Cosset <i>et al.</i> (1995); Markowitz <i>et al.</i> (1988); Miller <i>et al.</i> (1991)
		Addition of peptides: — Erythropoietin — Heregulin — Epidermal growth factor	Erythropoietin receptor Heregulin receptor Epidermal growth factor receptor	Han <i>et al.</i> (1995); Kasahara <i>et al.</i> (1994); Tai <i>et al.</i> (2003)
	Lentivirus	Pseudotyping entire envelope with envelope of vesicular stomatitis virus G	Improves infectivity to muscle	Gregory <i>et al.</i> (2004)
		Rabies 6 envelope	Improves infectivity to motor neurons	Mazarakis <i>et al.</i> (2001)
		Ebola	Improves infectivity for airway epithelial cells	Kobinger <i>et al.</i> (2001)
		Hantavirus	Improves infectivity to endothelium	Qian <i>et al.</i> (2006)
		Fowl plague hemagglutinin (with expression of influenza M2 protein)	Improves infection in airway epithelial cells	McKay <i>et al.</i> (2006)
	Adenovirus	Cationic lipids, cholesterol, polycationic polymers	Modify tropism	Fasbender <i>et al.</i> (1997); Worgall <i>et al.</i> (2000)
		Polyethylene glycol	Decrease immunity	
		Coupling of U7 peptide to Ad5	Targeting of urokinase plasminogen activator receptor on airway cells	Drapkin <i>et al.</i> (2000)
	Adeno-associated virus	Addition of single-chain antibodies	Target antibody ligand-expressing cells	Hedley <i>et al.</i> (2006)
		Chemical conjugation of avidin-linked ligands to AAV2	Targeting to ligand receptors	Ponnazhagan <i>et al.</i> (2002)
		Incorporation of bispecific antibody to AAV2	Targeting to human megakaryocytes	Bartlett <i>et al.</i> (1999)
	Lentivirus	Polyethylene glycol	Prolonging half-life in serum by preventing inactivation	Croyle <i>et al.</i> (2004)
	Retrovirus	Addition of single-chain antibodies	Target antibody ligands	Marin <i>et al.</i> (1996)

<sup>1</sup>CAR — coxsackie adenovirus receptor.<sup>2</sup>RGD — integrin-binding peptide arginine (R), glycine (G), aspartate (D).<sup>3</sup>CAV2 — canine adenovirus 2 (McCarty *et al.*, 2004; Qing *et al.*, 1999; Summerford *et al.*, 1999; Summerford and Samulski, 1998).<sup>4</sup>VSV — vesicular stomatitis virus (McCarty *et al.*, 2004; Qing *et al.*, 1999; Summerford *et al.*, 1999; Summerford and Samulski, 1998).<sup>5</sup>L14 — integrin-binding motif.

**FIG. 34.4.** Examples of modifications of tropism of gene transfer vectors. Shown are three examples of modification of adenovirus vector tropism. **(A)** The addition of polylysine to the Ad fiber protein provides broad tropism. **(B)** The addition of the integrin-binding motif RGD enhances targeting of cells expressing  $\alpha_v\beta_3$  integrins. **(C)** The addition of single-chain antibodies to the Ad fiber targets cells expressing the antibody ligand. Strategies A  $\equiv$  C provide broad to narrow cell-specific targeting.

(Work *et al.*, 2004). Finally, a capsid-modified Ad/AAV hybrid vector was able to achieve long-term expression in human hematopoietic cells (Shayakhmetov *et al.*, 2002).

Besides genetic modification of gene therapy vectors to modify tropism and target vector uptake to a particular cell type, chemical modifications of Ad vectors have been utilized for targeting. Ad vectors have been complexed to cationic lipids, polycationic polymers, or cholesterol to increase the efficiency of gene transfer *in vitro* and *in vivo* (Fasbender *et al.*, 1997; Worgall *et al.*, 2000). Bispecific monoclonal antibodies have been added to the fiber to target specific cell types expressing the ligand for that antibody.

### Targeting of AAV Vectors

The strategy of creating AAV chimeras by pseudotyping with capsids of different AAV serotypes has been used to broaden the tropism of AAV vectors (Bowles *et al.*, 2003; Hauck *et al.*, 2003; Rabinowitz *et al.*, 2002). Most of these vectors used the vector genome derived from AAV2 with the capsid from another serotype. For example, this strategy has enabled enhanced transduction in lung-directed gene transfer using an AAV5 pseudotype (Zabner *et al.*, 2000).

### Targeting of Retroviral and Lentiviral Vectors

The classic method to broaden the tropism of retroviral and lentiviral vectors is by pseudotyping, creating chimeras using envelope glycoproteins from other viruses. Most retrovirus vectors are based on MuMoLV, an ecotropic virus, which infects only murine cells. To achieve infection of human cells, the vectors are propagated in packaging cells that express the envelope of the amphotropic or nonmurine viruses, such as 4070A murine leukemia virus, gibbon ape leukemia virus, vesicular stomatitis virus (VSV), or the feline endogenous virus RD114 (Markowitz *et al.*, 1988; Miller *et al.*, 1991). Various envelopes have also been used for lentiviral vectors to increase infectivity of specific cell types, including VSV-G for muscle (Gregory *et al.*, 2004), Ebola for

airway epithelial cells (Kobinger *et al.*, 2001; Medina *et al.*, 2003), rabies-G for motor neurons (Mazarakis *et al.*, 2001), and hantavirus for endothelium (Qian *et al.*, 2006). Hybrid proteins of the murine amphotropic envelope have been combined with the extracellular domains of GALV or RD114 envelope to enhance infection of CD34+ cells (Sandrin *et al.*, 2002). As with Ad vectors, strategies have been developed to target retro- and lentiviral vectors by addition of ligands to the envelope glycoprotein. Examples include peptide sequences from erythropoietin (Kasahara *et al.*, 1994), heregulin (Han *et al.*, 1995), epithelial growth factor and ligands for the Ram-1 phosphate transporter (Cosset *et al.*, 1995), as well as the addition of single-chain antibodies (Marin *et al.*, 1996; Tai *et al.*, 2003). The efficiency of these modifications, however, has not been very high, and the vector production yield is significantly impaired.

Another strategy has been to utilize the membrane proteins that are incorporated during the budding process for targeting. For example, incorporation of the membrane-bound stem cell factor not only provided a growth signal for the CD34+ cells expressing c-kit, the receptor for stem cell factor, but also led to increased infection efficiency of the CD34 cells (Chandrasekran *et al.*, 2004). Monomethoxy poly(ethylene) glycol conjugated to VSV-G protects the vector from inactivation in the serum, leading to a prolonged half-life and increased transduction of bone marrow following intravenous administration in mice (Croyle *et al.*, 2004). Another strategy for targeting of retro- and lentiviruses *in vivo* has been to target retrovirus producer cells (Crittenden *et al.*, 2003).

## VII. REGULATED EXPRESSION OF THE TRANSFERRED GENE

A variety of strategies have been developed to regulate expression of the genes transferred by gene therapy vectors (Table 34.4). The ability to regulate gene expression is

**Table 34.4.** Regulation of expression of the transferred gene

Category	Strategy	Note	References
Inducible promoter	Glucocorticoid — responsive	Multiple response elements	Narumi <i>et al.</i> (1998)
	cGMP <sup>1</sup> — responsive	Multiple response elements	Suzuki <i>et al.</i> (1996, 1997)
	Heat shock protein — inducible	Hyperthermia and cellular stress induce gene expression	Isomoto <i>et al.</i> (2006); Luo <i>et al.</i> (2004)
	Radiation — inducible		Kufe and Weichselbaum (2003)
	Insulin — responsive		X. P. Wang <i>et al.</i> (2004)
	Tetracycline — responsive	Repressible-TET <sub>off</sub> or inducible-TET <sub>on</sub> systems	Auricchio <i>et al.</i> (2001); Fitzsimons <i>et al.</i> (2001); Haberman <i>et al.</i> (1998); Hofmann <i>et al.</i> (1996); Kafrie <i>et al.</i> (2000); Reiser <i>et al.</i> (2000); Rendahl <i>et al.</i> (2002)
	Antibiotic resistance	Streptogramin-class antibiotic (e.g., pristinamycin) induces pristinamycin-induced protein, preventing expression	Fussenegger <i>et al.</i> (2000)

particularly important for application where too much expression of the gene transfer product could lead to unwanted effects, e.g., sustained expression of a growth factor, which could potentially be tumorigenic. For *in vivo* strategies of gene transfer, tissue-specific regulation of gene expression may be warranted to avoid expression of genes in undesired cells or tissues. In the context of the use of gene transfer vectors to genetically modify stem cells, regulation of gene expression may be critical to avoid differentiation into an unwanted tissue or cell type. The regulation of the gene expression of the transgene could also be combined with inducible systems of suicide genes or factors that could destroy the genetically modified cells, should unwanted differentiation occur.

To turn gene expression on and off at will, a number of inducible promoters and inducible regulated systems have been developed that are applicable to be used in gene transfer vectors (Table 34.4). For example, inducible gene expression in gene transfer vectors can be achieved using inducible promoters, such as promoters responsive to glucocorticoids, cGMP, heat shock protein, radiation, and insulin. Inducible regulated systems also include systems based on response to tetracycline, antibiotic resistance, chemical-induced dimerization, steroid receptors, and insect ecdysone receptors. The basic mechanism for these systems is a combination of ligand-binding synthetic inducer or repressor proteins and a promoter control system that regulates transgene expression.

The tetracycline-responsive system has been widely used to study gene function and to generate conditional mutants in cell lines and transgenic animals (Gossen *et al.*, 1995). The transgene is placed behind a promoter that also contains binding sites for the tetracycline response element (TRE), which can act as a repressor or inducer of transgene expression. A fusion protein that binds to the inducer doxycycline needs to be present on a separate gene construct. The tetracycline transactivator binds to the TRE and activates the transcription in the absence of doxycycline. Upon addition of doxycycline, the expression is turned off (Tet-off). Another fusion protein that can be used is the reverse tetracycline transactivator, which only binds to TRE in the presence of doxycycline, causing induction of expression upon addition of doxycycline (Tet-on). Expression can be controlled in a graded manner; the more doxycycline is added, the greater the level of suppression or induction. The disadvantage of this system is the potential side effects of doxycycline. The tetracycline system has been used for regulated gene transfer with gene therapy vectors, including Ad (Auricchio *et al.*, 2001; Molin *et al.*, 1998), AAV (Fitzsimons *et al.*, 2001; Haberman *et al.*, 1998; Rendahl *et al.*, 2002), retroviral (Paulus, 1996; Hofmann *et al.*, 1996), and lentiviral vectors (Kafri *et al.*, 2000; Reiser *et al.*, 2000).

The steroid receptor systems use a mifepristone-binding progesterone receptor fused to the DNA-binding domain of the yeast GAL4 protein and the transactivation domain from

the NfκB p65 subunit (Ngan *et al.*, 2002; Y. Wang *et al.*, 1994). The fusion protein binds to a GAL4-activating sequence to regulate gene expression. Upon addition of mifepristone, gene expression is induced; upon removal of the drug, gene expression returns to baseline within five days.

The insect ecdysone receptor system consists of a fusion protein of the transactivation domain of the glucocorticoid receptor fused to the ecdysone-binding nuclear receptor and an ecdysone-response element placed upstream of the promoter driving the transgene expression (Hoppe *et al.*, 2000; Karzenowski *et al.*, 2005). Upon addition of ecdysone, an insect hormone with no mammalian homologs, the fusion protein dimerizes and induces expression. Because there are no known mammalian factors binding to the insect protein, there is very low background expression in the absence of the drug, and expression can be very tightly controlled.

Another strategy to control gene expression at the desired location is the use of tissue-specific promoters (Table 34.4). The majority of tissue-specific promoters have been used to target expression to liver and the cardiovascular system by targeting muscle cells. The challenge in the use of tissue-specific promoters is that the level of expression is usually lower than for the commonly used strong viral promoters. However, viral promoters such as CMV have been shown to be subject to silencing after several weeks *in vivo*. This has been seen in airways, cardiomyocytes, and smooth muscle cells, in particular with nonviral gene transfer (Dean, 2005).

Another modality to regulate gene expression is by *trans*-splicing at the pre-mRNA level. In therapeutic *trans*-splicing, the sequence of the target pre-mRNA is modified by being *trans*-spliced to an independent pre-mRNA, the sequences for which are delivered exogenously by a gene transfer vector (Pergolizzi and Crystal, 2004; Puttaraju *et al.*, 1999). Therapeutic *trans*-splicing can be used to alter coding domains, to create novel fusion proteins, to direct gene products to various cellular compartments, and to enable gene therapy with large genes or genes coding for toxic products. *Trans*-splicing gene transfer strategies also offer the advantage that the expression of the *trans*-spliced sequence is controlled by endogenous regulation of the target pre-mRNA. *Trans*-splicing strategies have been used to correct animal models of hemophilia, X-linked immunodeficiency with hyper IgM, and cystic fibrosis (Chao *et al.*, 2003; Liu *et al.*, 2002; Tahara *et al.*, 2004).

## VIII. COMBINING GENE TRANSFER WITH STEM CELL STRATEGIES

In general, stem cells are categorized into embryonal stem cells, the bone marrow-derived stem/progenitor cells, including mesenchymal stem cells (MSC), endothelial progenitor cells (EPC), and the tissue-derived stem cell populations (Bryder *et al.*, 2006). Stem cells offer the potential for tissue regeneration, and combining gene therapy and stem

cell approaches is a promising strategy to direct the differentiation of stem cells in the desired cell type and to regulate and control growth and differentiation of the stem cell. Stem cells have the potential for both self-renewal and differentiation and are dependent on signals from their microenvironment that direct stem cell maintenance or differentiation. The precise spatial and temporal presentation of these signals is critically important in development and will most likely be the decisive factor in the success of stem cell therapies (Alsberg *et al.*, 2006). As the potential of stem cells to be used clinically becomes more realistic, gene transfer strategies may play a pivotal role in controlling stem cell growth, by either preventing uncontrolled growth or directing differentiation into specific cell types, and regulating gene expression. In addition, as more of the microenvironmental cues that control stem cell differentiation into the desired phenotypes become known, the use of gene transfer strategies to express or inhibit these signals becomes a viable strategy to support stem cell therapy. Three general areas can be currently envisioned for gene transfer to be helpful for stem cell therapies: (1) to control unwanted stem cell growth or differentiation, (2) to provide environmental cues for stem cell differentiation, and (3) to regulate gene expression. In addition gene transfer may also be useful in marking stem cells as a modality to track the cells and their progeny *in vivo* (Yoneyama *et al.*, 2006).

### Gene Transfer to Stem Cells

The challenges in developing gene transfer strategies for stem cells are: (1) how most efficiently to infect the cells; (2) gene silencing during differentiation; (3) whether gene expression should be transient or persistent; and (4) if gene expression is persistent, whether it should terminate once the cell has differentiated into the desired phenotype. Gene transfer has been accomplished for a variety of stem cell types. Human and murine embryonal stem cells have been successfully infected, with subsequent gene expression, with adenovirus, AAV, and lentiviral vectors (Wobus and Boheler, 2005). The reported efficiency for each of these vector systems is limited, however, requiring selection to obtain pure populations of genetically modified cells. Gene expression can be affected by subsequent differentiation of the cells, and it is not clear how the stem cell properties are affected by the various gene therapy modalities themselves without transgene expression. Bone marrow-derived endothelial progenitor and mesenchymal stem cells have been successfully transduced with the most commonly used gene therapy vectors (Kaji and Leiden, 2001).

### Gene Transfer to Control Uncontrolled Stem Cell Growth

Gene transfer strategies developed to control the growth of cells for cancer gene therapy applications can be applied to controlling unwanted growth of stem cells, in particular the risk of the development of teratomas with embryonic

stem cells. Some of the suicide gene transfer strategies, including the prodrug strategies using herpes simplex thymidine kinase (HSV-TK) (ganciclovir) and cytosine-deaminase (5-fluorocytosine) that lead to activation of cell death following administration of the prodrug may prove useful. Other suicide genes may be used with regulatable gene expression systems (as outlined earlier, Table 34.4) to control potential malignant stem cell growth, as long as there is no “leak” of baseline gene expression of the suicide gene.

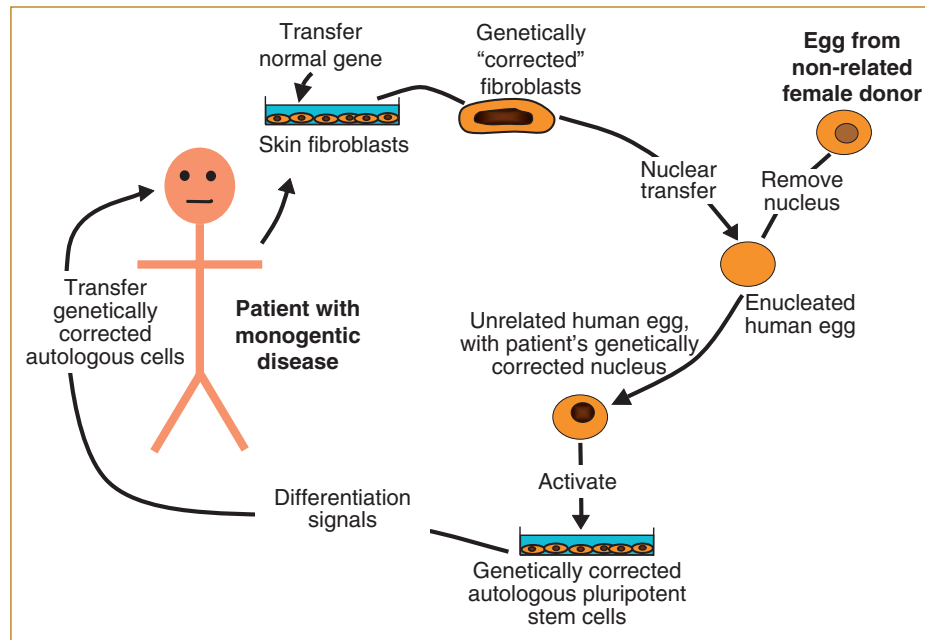

### Gene Transfer to Instruct Stem Cell Differentiation

Gene transfer strategies may prove useful in providing the environmental factors necessary to develop specific phenotypes from stem cells. For example, expression of growth factors or other known differentiation signals secreted by the stem cell should aid in mediating differentiation; i.e., the genetically modified stem cell would create its own favorable microenvironment for differentiation. Expression of these factors could be regulated by inducible gene expression systems. For example, for muscle-derived mesenchymal stem cells, with their potential for the treatment of skeletal, cardiac, and smooth muscle injuries and disease, the cytokines required for the differentiation in the respective lineage have been identified (Deasy *et al.*, 2002).

### Gene Transfer to Regulate Gene Expression

Regulation of gene expression is critically important in the maintenance and differentiation of stem cells, and the transfer of genes coding for factors that regulate endogenous gene expression in response to specific stimuli could prove very helpful for stem cell therapies. This concept has been used in gene transfer strategy to regulate angiogenesis in the ischemic myocardium. AAV vector-mediated transfer of a hypoxia, a responsive element to ischemic myocardium, resulted in endogenous expression of the vascular endothelial growth factor (VEGF) (Su *et al.*, 2002). Similarly engineered transcription factors capable of activating endogenous VEGF expression have been successfully transferred with adenoviral vectors (Rebar *et al.*, 2002). As more of the gene expression and regulation patterns critical for stem cell differentiation and maintenance are known, the possibilities to direct or aid in gene expression using gene transfer are significant.

One potential barrier to using embryonic stem cells in humans is rejection of the transplanted cell by the immune system (Fairchild *et al.*, 2004). This could theoretically be circumvented by using gene transfer with the relevant gene to autologous stem cells. For example, transfer of a genetically corrected nucleus to an enucleated egg from an unrelated donor would result in the generation of genetically modified embryonic stem cells, which could be then differentiated and the corrected, differentiated cells transplanted to the same patient (Fig. 34.5).

**FIG. 34.5.** Strategy to combine gene therapy with nuclear transfer and stem cell therapy. Shown is an example to genetically modify skin fibroblast of an individual with a monogenic disease, to correct the abnormality. The nucleus of the genetically corrected fibroblast is then transferred to an enucleated egg of an unrelated donor to generate corrected autologous pluripotent stem cells that can be differentiated and then transferred back to the patient.

## IX. CHALLENGES TO GENE THERAPY FOR TISSUE ENGINEERING

Although gene therapy has been proven very effective in a variety of model systems, the major challenges for gene therapy to cure human diseases include circumvention of immune responses against viral vectors, transferring the genes to a sufficient number of cells to change the phenotype, and controlling the expression of the gene. The main hurdle for successful gene therapy to compensate for a missing or defective protein has been the host response to the gene therapy vector, the lack of long-term gene expression, and problems related to integration into the host genome. However, short-term expression of transgenes has been feasible in humans and shown to be efficient in a variety of cell types and tissues. Immunogenicity against a

nonself transgene, as well as vector-derived proteins, may be an issue if gene transfer is being used for permanent expression of a transgene. Controlling the gene expression is a challenge that needs to be addressed, especially if gene transfer strategies are combined with stem cell strategies. Most regulatable gene expression systems show some baseline expression, which may be critical to eliminate, in particular to fine-tune the microenvironment for temporal expression of genetically transferred signals for stem cell strategies.

Over the past decade, progress has been made in addressing many of these challenges. Based on the continued focus on solving these issues, together with gene therapy, the knowledge gained from the successes and the setbacks will prove beneficial in their use for tissue-engineering and stem cell applications.

## X. ACKNOWLEDGMENTS

We thank N. Mohamed for help in preparing this manuscript. These studies were supported, in part, by U01

### I. INTRODUCTION

This chapter provides an overview of principles and barriers relevant to intracellular gene delivery by means of nanovehicles. The aim is to deliver a cargo to a particular intracellular site, if possible, to exert a local action. *Nanovehicles* are defined as a wide range of nanosized particles leading to colloidal objects capable of entering cells and tissues and delivering a cargo intracellularly. Different localization and targeting means are discussed. Limited discussion on pharmacokinetics and pharmacodynamics is also presented. Current nanotechnologies for gene delivery that are already in commercial use are also discussed. Newer developments in nanovector technologies are outlined, and future applications are stressed. Two issues are of prominent importance: lysosomal escape and subsequent cytoplasmic/nuclear delivery and intracellular polyplex stability. More complete treatments may be found in the references cited and in a more extensive review article (Prokop and Davidson, 2007) dealing with nanotechnologies relevant to both drug and gene delivery.

### II. GENE DELIVERY SYSTEMS

The design of delivery systems is an increasingly valuable discipline in pharmaceutical development, allowing rational manipulation of the pharmacological profiles of drugs and genes and their concomitant therapeutic indices. Delivery systems are now used to modify potentially therapeutic agents toward: (a) creation of new pharmaceutical moieties (e.g., liposomal gene delivery); (b) improvement in the effectiveness or reduction of the side effects of an existing therapeutic; (c) tissue-selective targeting (Mrsny, 2004); and (d) extension of the patent lifetime for an already marketed drug (Kostarelos, 2003). This is of advantage for drugs and gene products, which often exhibit a narrow therapeutic index, a short half-time in the bloodstream, and a high overall clearance rate. The *therapeutic index* is defined as the ratio of the toxic to the therapeutic dose of a drug.

#### Definitions

*Therapeutic agent* is defined as a chemical, biological, genetic, or radiological entity to be delivered to a disease

site for the purpose of treatment or detection (imaging). For the purpose of this chapter it is limited to genes and similar modalities.

The development of delivery systems able to alter the biological profiles (biodistribution, tissue uptake, pharmacokinetics, and pharmacodynamics) of therapeutic agents is considered of utmost importance in biomedical research and the pharmaceutical industry (Moses *et al.*, 2003). Definitions of biodistribution, the role of the reticuloendothelial system (RES), pharmacokinetics, pharmacodynamics, and bioavailability are expanded in a recent review (Prokop and Davidson, 2007). *Biodistribution* is the percentage of an administered dose that is deposited into specific organs throughout the body at specific time points. The tissue distribution of a particulate/macromolecular drug (gene) among different body locations is highly dependent on the nonspecific RES effects. The RES is the cellular system responsible for protection and clearance of “foreign” material. The RES consists primarily of phagocytic cells (e.g., midzonal and periportal Kupffer cells–liver macrophages) resident in the blood, liver, spleen, and lymph nodes as well as circulating monocytes. The RES is also called the mononuclear phagocytic system (MPS). The RES represents a preferential drug distribution site, following the first pass (Kostarelos, 2003). *Pharmacokinetics* is a study of the time course in the distribution of an administered drug concentration in the different organs throughout the body. *Pharmacodynamics* is a quantitative evaluation of any clinical parameter, such as body temperature, decrease in drug load, or therapeutic index, temporally fluctuating relative to the administered agent. *Bioavailability* is used to describe the fraction of an administered dose of medication that reaches the systemic circulation. Bioavailability is a measure of the rate and extent of a therapeutically active drug that reaches the systemic circulation after the first pass through the liver and is available at the site of action (Pond and Tozer, 1984). By definition, when a medication is administered intravenously, its bioavailability is 100%. However, when a medication is administered via other routes (such as orally), its bioavailability decreases (due to incomplete absorption and first-pass metabolism). Bioavailability is one of the essential considerations in pharmacokinetics, for bioavailability must be considered when calculating dosages for nonintravenous routes of administration. Even intravenous administration does not guarantee that a drug is freely available, because of plasma-protein binding. Drugs can bind to a variety of particles in the blood, including red blood cells, leukocytes, and platelets, in addition to proteins such as albumin (HSA), glycoproteins, basic drugs, including gene delivery vehicles, lipoproteins (neutral and basic drugs), and globulins (van de Waterbeemd and Gifford, 2003).

*Nanovehicles* (1–1000 nm) are typically composed of biodegradable and biocompatible polymers. Their degradation *in vivo* can occur over months to years (Okada and Toguchi, 1995) via enzymatic/hydrolytic scission mechanisms. For example, TCA cycle metabolism of PLGA and

related polymers can result in the biotolerable metabolites of lactic acid and glycolic acid. Nanovehicles often bind very efficiently to cells, internalized, and sorted into different organelles or cytoplasm, where they exert their function. Since gene products require an intracellular uptake for their function, such nanovehicles are typically used as means of their delivery.

Nanovehicles are thus defined as quasi-soluble, nanoparticulate delivery systems for intracellular delivery. Many different nanoparticulate technology platforms have been employed, each with different properties, strengths, and weaknesses. Most frequently discussed among these are polymer-based nanoparticulate platforms (Vicent and Duncan, 2006), dendrimers (Lee *et al.*, 2005), liposomes (Sato and Sunamoto, 1992; Bendas, 2001), gold nano-shells (Paciotti *et al.*, 2004), semiconductor nanocrystals (Q-dots; Akerman *et al.*, 2002), silicon- and silica-based nanosystems (Chen *et al.*, 2004), and superparamagnetic nanoparticulates (Ito *et al.*, 2005), among others. They can all be employed for gene delivery.

The fundamental opportunities for nanoparticulate delivery are summarized in three closely interrelated aspects: (1) the *recognition of target cells and tissues*, (2) the *ability to reach the diseased sites* where the target cells and tissues are located, and (3) the *ability to deliver multiple therapeutic agents*. The first two aspects comprise the notion of achieving preferred, substantially higher concentration of a therapeutic agent at site, a phenomenon that will be called *localization*, as opposed to the term *targeting*, which is often used to identify drugs that provide specific action against a target biological pathway (Ferrari, 2005a).

The nanovehicular systems offer certain distinct advantages for drug and gene delivery. Due to their subcellular and submicron size, nanovehicles can penetrate deep into tissues through fine capillaries, cross the fenestrations present in the epithelial lining (e.g., liver), and generally be taken up efficiently in cells. This allows efficient delivery of therapeutic agents to target sites in the body. Also, by modulating polymer characteristics, one can control the release of a therapeutic agent from nanovehicles to achieve the desired therapeutic level in the target tissue. Nanovehicles can be delivered to specific sites by means of conjugation or adsorption of a biospecific ligand. Localized delivery can improve the therapeutic index of drugs by minimizing the toxic effects to healthy (nondiseased) tissues/cells, largely depending on the extent of circulation time of nanovehicles in the central compartment (see below), the release rate, and the rate of uptake of nanovehicles (their internalization; see below).

## Intracellular Delivery: Pharmacokinetics

### Defining the Elementary Steps

1. *Removal from the circulation.* It is essential that the nanovehicle, loaded with a drug/gene, not be cleared too quickly from the circulation. Rapid clearance may

prevent the vehicle from reaching the required concentration at the site of localization. Many vehicles/drugs will bind to plasma components (principally HSA) or within other compartments of the tissue. Binding can greatly influence the transport and elimination in individual organs and can influence the overall pharmacokinetics.

2. *Release of free payload at nontargeted sites.* Depending on the amount of the gene/vector, the release of the gene/vector away from the target site could nullify any benefits that might potentially come from delivering the gene/vector to the target site.
3. *Delivery of the gene vehicle to the target site.* If the nanovehicle reaches the target site too slowly, the supply of contents might never be sufficient to generate the concentration required to elicit the desired therapeutic effect at the site of action (delivery window).
4. *Release of free payload at the target site.* The capacity of the system selected for the release of payload from the nanovehicle should be considered at a rate that also ensures drug accumulation at the target site.
5. *Removal of free payload from the target site.* Agents that benefit most from localized delivery are those that are retained at the site while acting on their target of action.
6. *Elimination of the vehicle from the body.* For optimal localization, elimination of the agent vehicle should be minimal. Nanovehicles and their payloads are typically eliminated via the kidneys, liver, and spleen, depending on their size and other properties.

Some useful details on these elementary steps and on mathematical modeling tools that encompass the foregoing considerations can be found in references by Petrak (2005) and Boddy *et al.* (1989).

### Pharmacokinetics

Pharmacokinetics and access to different compartments are of crucial importance for gene delivery.

### Fundamentals

Some fundamentals of pharmacokinetic (PK) modeling were summarized by Saltzman (2001). The goal of pharmacokinetics is synthesis into a coherent model of physical and biological phenomena involved in drug distribution in the body, although development of a comprehensive (elementary) model may not be practical. The four components of PK are commonly referred to as absorption, distribution, metabolism, and excretion (ADME). Being empirical, the utility of compartmental models is limited, because they are not valid beyond their experimental domain. In contrast, detailed physiological models often contain parameters that are difficult to measure. A physiological pharmacokinetic model may include a multiple-compartment approach, whereas each organ is composed of multiple subcompartments, reflecting the anatomy/morphology of the organ. In a typical pharmacological model, the target is accessible directly from the central compart-

ment (whereas delivery to a peripheral compartment is required in another case; e.g., in delivery to skin, muscle, peritoneum). The central compartment is defined as a blood/lymphatic circulation system. In the most favorable case, traditionally measured plasma drug concentration is connected with tissue distribution and pharmacokinetic measurements. The pharmacokinetic modeling may provide insights into appropriate dosing regimens (amount of drug, capacity, and dosing frequency), optimal binding affinity, and how receptor-mediated effects may be anticipated from natural or mimetic drug ligands (Mager *et al.*, 2006).

### Accessing the Tumor Compartment

The tumor compartment can be presented as a single entity composed of a vascular subcompartment with cell surface receptors and an intracellular tumor space (the target tissue). Nanovehicles accumulate in tumor tissue because of their extended circulation time in conjunction with preferential extravasation from leaky tumor vessels (EPR effect). The EPR effect features tumor hypervascularity, defective vascular architecture, and a deficient lymphatic drainage system. The attachment of the nanovehicle to the endothelium is either nonspecific or facilitated by a specific targeting (active targeting) motif directing nanovehicles to the tumor endothelium. This passive targeting process facilitates tumor tissue binding, followed by uptake (internalization). This phenomenon results in intracellular release of antitumor activity. Nanovehicles that fail to bind to tumor cells will reside in the extracellular (interstitial) space, where they eventually become destabilized because of enzymatic and phagocytic attack. This results in extracellular payload release, for eventual diffusion to nearby tumor cells and possible bystander effects. Targeted drug delivery systems may substantially affect both drug disposition and pharmacological properties.

### Lymphatic Administration

Lymphatic administration is a means of minimizing general systemic drug exposure to modify biodistribution. The primary function of the lymphatics is to drain the capillary beds and return extracellular fluid to the systemic circulation. Unlike the blood flow, lymph flow is single-pass, recovering fluid from the periphery and returning it to the vasculature. Drug transport through the lymph may be utilized to prolong the time course of drug delivery to the systemic circulation, bypassing liver and avoiding hepatic first-pass metabolism.

## III. EXPLORING THE ROLE OF RECEPTOR LIGAND SIGNALING AND RECEPTOR CLUSTERING IN AGENT DELIVERY

Cell surface receptors are complex transmembrane proteins that mediate highly specific interactions between cells and their extracellular milieu. The type, number, and functions of receptors are defined by cellular lineage, genet-

ics, and a number of extracellular factors. Since receptors are differentially expressed in various cells types and tissues, they provide potential targets for gene delivery. Receptors, however, not only are cellular markers, but play an integral role in the regulation of virtually all cellular functions, including growth, differentiation, metabolism, secretion, contraction, and migration.

Receptor binding is an area of potential importance to localized gene delivery, including endocytosis, transcytosis, ligand–receptor interactions, and receptor regulation. Since biochemical and physiological properties of receptors vary depending on both receptor type and cellular background, it is likely that some receptor systems may be more suitable than others for receptor-mediated drug delivery. Next, we review some basics of the cellular entry of macromolecules and particles (King and Feener, 1998).

### Taking Advantage of Receptor-Mediated Endocytosis and Signaling

An important function for receptors is to facilitate ligand internalization via receptor-mediated endocytosis. In this process, a ligand bound to its receptor is endocytosed from clathrin-coated pits on the plasma membrane, forming an endocytotic vesicle.

For localization of gene delivery vehicles, various endogenous ligands, such as peptides, proteins, lipoproteins, growth factors, vitamins, and carbohydrates, can be used. Folate, transferrin, and EGF receptors are good examples of such ligands.

### Employment of a Proper Receptor Repertoire for Delivery

While the initial events in the endocytosis of the receptor–ligand complex are similar for most systems, the processing of the ligand can differ, depending on both receptor and cell type. In most instances, the role of receptor-mediated endocytosis is to internalize ligands for their subsequent proteolytic degradation in the acidic pH of the endosomal compartment. The receptor is then recycled back to the plasma membrane, whereas the ligand is destined for lysosomal degradation. This proteolysis of ligand can serve to remove a signal or to clear an undesirable protein or delivery vehicle. Cells can also reduce the level of ligand stimulation both by degrading the ligand and by reducing the number of receptors expressed on the plasma membrane (down-regulation of receptors).

A more detailed understanding of the biochemical and physiological characteristics of receptors is necessary to avoid the undesirable effects of selected binding to these active cell surface proteins and to realize their full potential for receptor-mediated gene delivery. Receptors' primary functions are to mediate protein trafficking and to transduce signals across the cellular membrane. Studies of receptor structure have revealed specific domains and

motifs that regulate receptor trafficking, kinase activity, and coupling with intracellular signaling networks. These findings can be utilized at the design of gene delivery systems.

### Delivering Across the Cellular Barriers

Receptor-mediated transcytosis could be utilized as a method for the delivery of drugs and genes across cellular layers, including the blood–brain barrier (Olivier, 2005). In cells that are polarized into apical and basolateral surfaces, such as endothelial and epithelial cells, certain receptors can mediate transcytosis. This involves the vectorial trafficking of the ligand, via endocytic vesicles, across the cellular layer. A number of ligands have been reported to be transcytosed in these cell types, including insulin and EGF (Kurihara and Patridge, 1999; Brandli *et al.*, 1991; Shah and Shen, 1996). The role of transcytosis is to selectively facilitate the transport of ligands across diffusional barriers, such as the vascular endothelium.

### Employing Receptor Clustering

Transmembrane receptors are increasingly being found to be organized into higher-order structures in the cytoplasmic membrane (Bollinger *et al.*, 2005). Clustering may be an evolved strategy to achieve the greater effectiveness and/or higher strengthening of adhesion required by many biological functions other than uniform molecular distribution. Clustering renders high local densities of receptors and/or ligands, which may be independent of global or average densities, resulting in multiple bonds that do not obey existing criteria for receptor–ligand interaction. One desirable mechanism is thus multiple receptor interactions of ligands with multiple receptors on the cell surface.

One example of clustering effects is the family of transmembrane proteoglycans, the syndecans, which have important roles in cell adhesion. They participate in biological processes through binding of ligands to their glycosaminoglycan chains, clustering, and the induction of signaling cascades to modify the internal microfilament organization. Syndecans can modulate the type of adhesive responses induced by other matrix ligand–receptor interactions, such as those involving the integrins, and thus contribute to the control of cell morphology, adhesion, and migration. These proteoglycans have been used for localization of drug delivery vehicles.

Another example comes from a carbohydrate–carbohydrate and protein–glycan interaction. Characteristic features of these interactions are their specificity, their strong dependence on divalent cations, and their extreme low affinity, which has to be compensated by multivalent presentation of the ligands. Multivalent presentation (display) has been proved to be important in the study of carbohydrate–protein interaction (de la Fuente and Penades, 2004).

## IV. OVERVIEW OF NANOVEHICLE UPTAKE AND TRAFFICKING

### Background Information

The successful design of a delivery system requires a thorough understanding of the mechanisms involved in the interaction of the delivery systems with the target cells. In particular, an understanding of intracellular trafficking and targeting would help to design better and more efficient gene delivery systems. Intracellular targeting refers to the delivery of therapeutic agents to specific compartments or organelles within the cell. Endocytosis (and some other forms of uptake, phagocytosis) is considered the most useful mechanism to describe multiple forms of internalization. Because of many commonalities between drug and gene delivery systems, many references are cited on the behavior of drug delivery systems.

### Nanovehicle Size

Our studies and those of others show that particle size significantly affects cellular and tissue uptake; in some cell lines, only the submicron-size particles are taken up efficiently but not the larger microparticles (e.g., Win and Feng, 2005; Desai *et al.*, 1996; Zauner *et al.*, 2001; Rejman *et al.*, 2004). In Caco-2 cells the uptake of nanoparticles (PLGA with PVA coating) 100 nm in size was 2.3-fold greater as compared to that of 50-nm particles, 1.3-fold to that of 500-nm particles, and about 1.8-fold to that of 1000-nm particles. Thus, it has been demonstrated that nanoparticles 100–200 nm in size possess the best properties for cellular uptake (Win and Feng, 2005; Moghimi *et al.*, 2001).

### Spatial and Temporal Effects

Nanovehicle internalization is concentration and time dependent as well as cell-type dependent. Endocytosis results in internalization of the cell's plasma membrane, to form vesicles that capture macromolecules and particles present in the extracellular fluid and/or bound to membrane-associated receptors. These vesicles then undergo a complex series of fusion events directing the internalized cargo to an appropriate intracellular compartment (uptake of fluids, macromolecules, particles, and other ligands that sort to the cell's processing pathways). Uptake of particulate systems can occur through various processes, such as by phagocytosis, fluid-phase pinocytosis, transport via clathrin-coated pits, caveolae-mediated transport, and nonendocytic pathways. Transcytosis and exocytosis are pathways communicating with the cells' external environment (Panyam and Labhasetwar, 2003).

### Trafficking Phenomena

Following their uptake, nanovehicles have been shown to be transported to primary endosomes and then to sorting endosomes. From sorting endosomes, a fraction of nanove-

hicles are sorted back to the cell exterior through recycling endosomes (efflux, exocytosis), while the remaining fraction is transported to secondary endosomes, which then fuse with lysosomes. The nanovehicles then escape the endo-lysosomes and enter the cytosolic compartment. Time-dependent uptake studies showed that nanovehicles escaped the endo-lysosomes within 10 min of incubation and entered the cytoplasmic compartment. Selective surface-charge reversal of nanovehicles in the acidic pH of endo-lysosomes is proposed as the mechanism responsible for the endo-lysosomal escape of the nanoparticles. Surface-charge reversal results from the transfer of protons/hydrogen ions from bulk solution to the nanovehicle surface under acidic conditions. This is often due to the typical cationic charge of the nanovehicle periphery, leading to localized destabilization of the membrane and the escape of nanoparticles into the cytoplasmic compartment. Polystyrene nanoparticles, which do not exhibit surface-charge reversal with a change in pH, were not seen escaping the endo-lysosomal compartment (Panyam and Labhasetwar, 2004).

### Exocytosis

Nanovehicle amounts inside the cell are maintained as long as nanovehicles are present in the outside medium. Once the external concentration gradient is removed, exocytosis of intact nanovehicles begins and results in a substantial drop in a matter of minutes. However, at least some initial nanovehicle levels are maintained over several hours of incubation *in vitro*. Some researchers have observed that a nanovehicle exocytosis was inhibited in serum-free medium. Protein (albumin) present in the serum was found to be responsible for inducing nanovehicle exocytosis (Panyam *et al.*, 2003). Very little information is available on nanovehicle exocytosis.

### Are *In Vitro* Data Translatable to *In Vivo*?

The translation of the *in vitro* data to the *in vivo* situation is not always straightforward. One can infer the internalization of nanovehicles from experiments on gene delivery as well as from those that follow the localization of nanovehicles in tissues and cells. This detection is possible due to recent developments in labeling and imaging. The intracellular localization of nanovehicles in tissues is not easily obtained.

### Mechanisms of Nanovehicle Uptake and Efflux

Endocytosis occurs by multiple mechanisms that fall into two broad categories: *phagocytosis*, or cell eating (the uptake of large particles), and *pinocytosis*, or cell drinking (the uptake of fluid and solutes) (Conner and Schmid, 2002). Specialized efflux mechanisms serve to dispose of drugs and the nanovehicles. A summary of different mechanisms is presented in Table 35.1.

**Table 35.1.** Efficiency of nanovehicle entry via multiple portals as differentiated by cargo chemistry/size<sup>a</sup> and cell type

<i>Phagocytosis</i>		<i>Pinocytosis</i>				
		<i>Macropinocytosis (fluid phase)</i>	<i>Clathrin- mediated (CME)</i>	<i>Caveolae- mediated rafts</i>	<i>Lipid rafts</i>	<i>Clathrin- and Caveolin- independent</i>
Vehicle size	1–10 $\mu\text{m}^b$	1–5 $\mu\text{m}^b$	<150 nm	<60 nm	40–60 nm	200–300 nm
Cell types	Dendritic, macrophages, monocytes	Many cells	Many cells	Differentiated endothelial cells, adipocytes, epithelial, and muscle cells	Lymphocytes, cancer cells, rodent macrophages	Specialized cells, endothelial cells, and others
Efficiency of uptake <sup>c</sup>	+++++ for specialized cells	+++	+++++	+	+	++++

<sup>a</sup>Typically, cargo chemistry determines a size range due to technological limitations (e.g., dendrimer-based and micellar-based nanovehicles are limited to rather small sizes).

<sup>b</sup>Phagocytosis and macropinocytosis most likely do not contribute to the nanovehicular uptake.

<sup>c</sup>The efficiency of uptake may depend on NV type and chemistry. The proportion between different uptake mechanisms may vary. Estimated on scale of 1–5, 5 being the highest.

### Phagocytosis (PC)

Phagocytosis is typically restricted to specialized mammalian cells (dendritic, macrophages, monocytes, and neutrophils), whereas pinocytosis occurs in all cells by at least five basic morphological distinct mechanisms: macropinocytosis (MPC), clathrin-mediated endocytosis (CME), caveolae-mediated endocytosis (CavME), lipid raft-mediated endocytosis (LRME), and clathrin- and caveolae-independent endocytosis (CCLIE).

### Macropinocytosis (MPC), or Fluid-Phase Endocytosis

Macropinocytosis can be measured by the intracellular accumulation of a tracer molecule present in the medium. The degree of internalization of fluid-phase markers is directly proportional to their concentration in the medium and the volume encased by the transport vesicles. Greater efficiency of endocytosis is achieved by nonspecific binding of solutes to the cell membrane (adsorptive pinocytosis), but the most efficient uptake occurs when dilute solutes are captured by specific high-affinity receptors (receptor-mediated endocytosis), which are themselves concentrated into specialized endocytic transport vesicles. Macropinocytosis is accompanied by membrane ruffling and protrusion formation, which then collapse onto and fuse with the plasma membrane to generate large endocytic vesicles called *macropinosomes* (>1  $\mu\text{m}$  in size, up to 5  $\mu\text{m}$ ), which sample large volumes of the extracellular milieu.

Macropinocytosis is generally considered a non-receptor-mediated process (nonspecific), where cells take up large volumes of extracellular fluids and solutes. It is constitutive in highly specialized cells (macrophages and dendritic cells) and in some tumors, and it can be induced by growth factors in epithelial cells. It is the principal endocytic pathway in endothelial cells (EC). Although the pH of macropinosomes decreases, they do not fuse into lysosomes. This pathway provides some advantageous aspects, such as the increased uptake of particles and macromolecules, the avoidance of lysosomal degradation, and the ease of escape from macropinosomes because of their relatively leaky nature.

### Clathrin-Mediated Endocytosis (CME)

CME occurs constitutively in all mammalian cells, and it carries out the continuous uptake of essential nutrients, antigens, growth factors, and pathogens. Clathrin-coated vesicles of the CME pathway carry concentrated receptor-ligand complexes into the cells. They range in size from 100 to 150 nm in diameter. Molecules entering via this pathway will rapidly experience a drop in pH from neutral to pH 5.9–6.0 in the lumen of early endosomes, with a further reduction to pH 5 during progression from late endosomes to lysosomes (Maxfield and McGraw, 2004). Ligands and receptors are then sorted to their appropriate cellular destinations, such as lysosomes, the Golgi apparatus, the nucleus, or the cell surface membrane. Some portion of the

receptor–ligand complex also recycles back, via what is called *exocytosis* (Goldstein *et al.*, 1985).

#### Caveolar-Mediated Endocytosis (CavME)

Caveolae are flask-shaped invaginations (50–60 nm in size) of the plasma membrane that are typically seen on the surface of endothelial cells, where they are extremely abundant. Caveolae are derived from the Golgi complex and are now known to be present on many specialized cells and to demarcate cholesterol- and sphingolipid-rich microdomains of the plasma membrane, in which many diverse signaling molecules and membrane transporters are concentrated (Sangiorgio *et al.*, 2004). A major difference from CME is that the caveolar uptake is a nonacidic and nondigestive route of internalization, bypassing lysosomes, potentially a route of advantage for drug delivery. However, caveolae are internalized slowly and are small in size, and their fluid-phase volume is small; this results in *low-capacity uptake*. Thus, it is unlikely that they contribute significantly to constitutive endocytosis, although the situation is different in endothelial cells, in which caveolae constitute 10–20% of the cell surface (Conner and Schmid, 2002).

#### Lipid Rafts–Mediated Uptake (LRME)

For anionic and neutral-lipid liposomes, solid-lipid nanoparticles, and hydrophobic nanoparticles (e.g., synthetic polystyrene nanoparticles) there is another potential pathway, endocytosis-independent uptake. Lipid rafts are small (40–60 nm in diameter) and free cholesterol- and sphingolipid-rich planar microdomains characteristic of cell surfaces that lack caveolin and caveolae, such as lymphocytes, many human cancer cells, and rodent macrophages. A hydrophobic uptake via the lipid membrane fusion is likely to be involved. The likely mechanism is that of the scavenger receptor, involved in the uptake of both lipophilic and anionic groups (Fabriek *et al.*, 2005). Scavenger receptor class B (SRB1; CD36 superfamily of proteins), expressed on mature macrophages, is particularly promiscuous, and ligands include proteins, polyribonucleotides, polysaccharides, and lipids, for which the main common feature is that they are “polyanionic.” The involvement of SRB1 in liposome uptake was demonstrated on the basis of polyinosinic acid (a strong polyanion) competitive abolishment of the association of neutral phospholipids/cholesterol liposomes with hepatic cells (Adrian *et al.*, 2006). As expected, anionically charged liposomes (heparin-functionalized) exhibit an extended circulation time and provide better pharmacokinetics for encapsulated doxorubicin (Dox), following their intravenous injection in mice (Han *et al.*, 2006). It appears that the lipid raft–mediated fusion is facilitated by a transbilayer membrane potential that exists across cell membranes. This constitutes a major difference between the caveolae- and lipid raft–mediated endocytosis: They lack an energy input requirement for lipid raft–mediated uptake, a strong argument for this distinction, although

not universal. In addition, this type of uptake features bypassing of the lysosomal compartment, of significance for gene delivery.

#### Clathrin- and Caveolae-Independent Endocytosis (Nonendocytic Pathway) (CCLIE)

The recently discovered clathrin- and caveoli-independent pathway is of significance for ICAM-1-positive cells (CAM-mediated endocytosis; Muro *et al.*, 2004). Nanovehicles coated with anti-ICAM antibody induce ICAM-1 clustering by multivalent nanovehicle presentation. CAM-mediated endocytosis delivers materials to lysosomes (Muro *et al.*, 2006a). CAM-1, a transmembrane glycoprotein from the Ig-like superfamily of adhesion molecules, which is up-regulated and functionally involved in inflammation and thrombosis, may provide a unique target for lysosomal disease (LSD). It is expressed by cell types affected in the diverse forms of LSDs, including endothelial (EC), epithelial, glial, and Schwann cells; leukocytes; myocytes; and other cells. However, ICAM-1 and another Ig superfamily cell adhesion molecule, platelet endothelial cell adhesion molecule-1 (PECAM-1), are not readily internalized by endothelial cells. Little is known about the intracellular trafficking and fate of anti-CAM nanoparticles. Muro and others have also reported on a “monensin-switch” modulation (via  $\text{Na}^+/\text{H}^+$  exchanger), allowing the bypassing of lysosomes, with the potential of improving drug cytoplasmic efficacy (Muro *et al.*, 2006b).

#### Exocytosis (EC)

Exocytosis is a constitutive mechanism of metabolite elimination for every cell. It may be also operational for nanovehicles. Limited studies are available at this point, however. The underlying observation is that once the cells are devoid of any external reservoir of nanovehicles for uptake, once-internalized nanovehicles leave the intracellular sites and are expelled outside (Panyam *et al.*, 2003). This is probably because of the high local concentration of nanovehicles in the vicinity of cell membranes, resulting in their internalization, along with extracellular liquid and solutes, into the cell through endocytosis (pinocytosis). Recent observations testify to the role of targeting ligands associated with nanovehicles in exocytosis. Sahoo and Labhasetwar (2003) observed decreased exocytosis for Trf-conjugated PLGA nanoparticles, as compared to nonfunctionalized ones. Salaün *et al.* (2004) argue that there is a constitutive exocytosis pathway operating in all cells, in addition to a regulated one, facilitated by lipid rafts and cholesterol- and sphingolipid-rich microdomains, enriched in the plasma membrane. This constitutive pathway may be of significance for liposomal gene delivery.

#### Transcytosis (TC)

Transcytosis reflects transport across the endothelial (and epithelial) cells to the subendothelial space. For trans-

cellular transport, drugs need to cross two different membranes on the basal and apical sides. In the intestine, drugs are absorbed from the luminal side (brush border membrane) and excreted into the portal blood across the basolateral membrane. The endocytosis on the apical (luminal) surfaces is followed by transport through a series of intercellular compartments and delivery to the basolateral (abluminal) plasma surface, where the substances are secreted or diffused via intercellular junctions (paracellular transport). Transporters are thus important as a determinant of the clearance in the body (Shitara *et al.*, 2006). The process of caveolar-mediated endocytosis is highly inefficient, as observed on passage through the gastrointestinal tract and brain–blood barrier (BBB), amounting to less than 1–2% of the luminal input (Florence and Hussain, 2001). Transcytosis of nanovehicles has been also documented (Oberdoster *et al.*, 2005; Florence and Hussain, 2001).

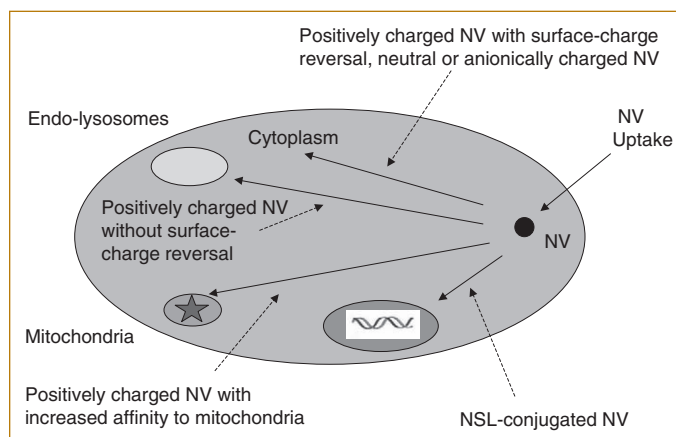

### Conclusions About Nanovehicular Uptake

Concluding on the foregoing portals of entry of nanovehicular drugs/vehicles, there is accumulating evidence that different endocytic pathways merge and are connected to the same early endosome that serves as a distribution site inside the cells. The cargo may be delivered to internal organelles (caveosomes) from noncaveolar uptake mechanisms (Sharma *et al.*, 2002). There are no definitive answers to all questions in terms of involvement of a certain trafficking pathway in different cells. Considerable confusion exists because many endocytosis studies relied on the use of pharmacological agents whose specificity remains a matter of debate. In addition, many artifacts have been generated and reported because of improper cell fixation prior to microscopic observation of the cells. The prevalent view is that the cargo (payload) also influences the type of uptake mechanism and trafficking (Johannes and Lamaze, 2002). A schematic illustration of different uptake/exocytosis mechanisms is depicted in Fig. 35.1. Figure 35.2 presents possible routes of the intracellular fate of nanovehicles.

Kinetically, three modes of endocytosis can be defined: fluid-phase, adsorptive, and receptor-mediated endocytosis (Amyere *et al.*, 2002). *Fluid-phase endocytosis* refers to the bulk uptake of solutes in exact proportion to their concentration in the extracellular fluid. This is a low-efficiency and nonspecific process. In contrast, in *adsorptive* and *receptor-mediated endocytosis*, macromolecules are bound to the cell surface and concentrated before internalization. In adsorptive endocytosis, molecules preferentially interact with generic complementary binding sites (e.g., by HSPG, lectin, or charged interaction) in a nonspecific manner. Such a distinction is of practical interest because of the uncertainties of the intimate uptake mechanism, as discussed earlier. Fluid-phase endocytosis has a lower internalization capability than adsorptive endocytosis.

## V. STABILITY OF NANOVECTORS IN BUFFERS AND BIOLOGICAL FLUIDS: STERIC VS. ELECTROSTATIC STABILIZATION

### Steric Stabilization

To be effective for delivery, nanovehicles must remain in a colloidal form. This requires the minimization of interparticle interactions. To avoid nonspecific aggregation under physiological conditions, the long-term stability of the nanovehicles represents a serious problem (Moghimi, 2002). Steric stabilization is defined as reduction in particle

interactions by means of a surface steric barrier. The prevailing view is that repulsive forces result from the “compression” of tethered layers presented on the nanovehicle surface. In addition, the hydrophilic side chains extending outward from the particle surface provide stability to the particle suspension via a repulsion effect through a steric mechanism of stabilization involving both enthalpic and entropic contributions, while the dimension of the stabilizing chains exceeds the range of Van der Waals force of attraction. Macrophages express surface receptors that do not recognize or internalize sterically protected nanovehicles.

### Electrostatic and Combined Stabilization

In contrast to the kinetic stability achieved by electrically neutral polymers, electrostatic stabilization employs repulsive, coulombic interactions between the charged surfaces (Pincus, 1991; Einarson and Berg, 1993). Note that most nanovehicles are endowed with a charge. Any ionizable groups in the hydrophilic domains presented at the nanovehicle periphery act as electrostatic stabilizers. This method is sensitive to dissolved salts, which suppress the screening effect. A coupled mechanism involving both electrostatic and steric mechanisms is denoted as *electrosteric stabilization*. A good example is the employment of anionic copolymers with suitably sized PEG molecules. Attached to gene delivery vectors via a coating, such complexes readily prevent opsonization by serum proteins, maintain their size, and do not aggregate at near electroneutrality (low zeta potential) (Finsinger *et al.*, 2000).

The stability of the electrostatic complex (the most frequently employed form of delivery for DNA; see before) *in vivo* is another issue. In general, PEC stability in plasma could present a problem. PLL/DNA complexes (poly L-lactate)/DNA can undergo rapid clearance from the plasma following intravenous administration. The plasma proteins, particularly serum albumin, can loosen the complexes and enlarge them. Dash *et al.* (1999) reported on the possibility of ternary complex between PLL/DNA and albumin that can undergo a disruption by positively charged serum proteins at physiological pH. All forms of PEC complexes may require stabilization to improve their circulation times *in vivo*. Cationic polymers with short side chains were shown to form smaller complexes, resistant to destabilization by polyanions. The destabilization of cationic lipid/DNA complexes *in vitro* and in plasma by HSPG polymers and heparin facilitates DNA release (Wiethoff *et al.*, 2001; Chittimalla *et al.*, 2005). The multicomponent PEC-based nanoparticles (Prokop *et al.*, 2002a, 2000b) are more resistant to the interpolyelectrolyte exchange mechanism (competitive displacement of the components of the polyelectrolyte complex with other charged species, external polyelectrolytes, and small ions). The inter-polyelectrolyte exchange often leads to unpacking of the assembled particle (Zelikin *et al.*, 2003).

The PEC complex is considered a result of a reversible monomolecular reaction, while there is a competition between complexation and counterion binding. The multicomponent system apparently results from an interaction of two pairs of polyelectrolytes. Oupicky *et al.* (2002) demonstrated an increased resistance to polyelectrolyte exchange and prolonged plasma circulation time for polycation/DNA polyplexes modified with multivalent PHPMA [*N*-(2-hydroxypropyl)methacrylamine] laterally cross-linked polymer (of the surface of polyplex), for the presence of PEG molecules only has no beneficial effect on susceptibility to the polyelectrolyte exchange reaction. The stability of the intracellular complex should also be checked (Breunig *et al.*, 2006).

## VI. LOCALIZATION AND TARGETING

Ferrari (2005b) introduced a concept of localization and employment of additive, multimodal localization strategies, because they are noninterfering and each contributes favorably to the achievement of preferred spatial concentrations.

### Localization

#### Localization by Size and Shape

This is applicable to liposomes, where it has been demonstrated that tailoring nanovector size to match the fenestrations of the cancer neovasculature yields preferential concentration at tumor sites — a phenomenon termed *enhanced penetration and retention* (EPR).

#### Localization by Physical Properties

The surface charge of nanovectors influences tumor uptake. Differences between positively vs. negatively charged nanovectors have been noted. Several investigators demonstrated that negatively charged nanovehicles were distributed away from the RES system (Roser *et al.*, 1998; Yang and Zhu, 2002; Furumoto *et al.*, 2004), as opposed to the characteristic behavior of cationically charged nanovectors, which are typical in gene delivery.

#### Localization by Remote or Environmental Activation

Regardless of the details of the distribution of injected nanovectors in the body, exquisite localization of the effect may be attained if the agent is activated only at the intended target sites by irradiation with an exogenous and locally focused source of energy. An excellent example of remote activation is a TNFerade Biologic™, an adenovirus carrying the TNF $\alpha$  gene under the control of a radiation-inducible promoter (McLoughlin *et al.*, 2005). It has entered phase II trials, where an intratumoral injection is used in combination with radiotherapy. In this way, control of different spatial and temporal levels is achieved.

## Targeting

Selective delivery and prolonged retention is desired via the control of the pharmacological parameters characteristic of the administered moieties. This can be achieved by designing delivery systems that either (a) enhance the deposition or accumulation of the therapeutic in a particular tissue; (b) associate the therapeutic with a particular cell population; (c) associate the therapeutic with a specific intracellular component; or (d) prolong the association of the therapeutic within a specific organ (e.g., brain, blood); or (e) any combination of these (Kostarelos, 2003).

### Active Targeting

This targeting refers to delivery systems designed to associate or interact with specific biological moieties, most commonly by attachment on their outer surface of ligands (peptides, antibodies, antibody fragments, and proteins) with an enhanced binding affinity for cellular receptors or surface matrix molecules. Besides a higher binding affinity, one should distinguish between the binding, enhanced vehicle internalization, and subsequent downstream biological activity.

### Passive Targeting

This targeting refers to all strategies attempting to achieve defined delivery without utilizing specific biological (ligand–receptor) interactions accompanied by correlating the physicochemical and surface characteristics of the delivery systems with the pathophysiology and anatomy of the target sites. Illustrative examples of passive targeting include the extravasation of sterically stabilized nanoparticles from leaky tumor capillaries into the interstitium, and the extended blood circulation half-lives of polymer-coated moieties (proteins, drugs, and liposomes). Passive targeting of macromolecular drugs, including gene delivery vectors, to tumors can be achieved by the EPR effect (Gunther *et al.*, 2005).

### Externally Stimulated Targeting

The third type of targeting, gradually becoming more commonly studied, can be termed *externally stimulated targeting*, whereby localization of the therapeutic agent at a specific site is achieved by an externally applied stimulus, such as temperature, light, ultrasound, ionizing radiation, or magnetic force (Minko *et al.*, 2004).

### Intracellular Targeting

Nanovectors can be used as efficient delivery vehicles for intracellular targeting. Types of intracellular targeting include (a) endo-lysosomal, (b) cytoplasmic, (c) cytoskeletal and caveolar, (d) mitochondrial, and (e) nuclear. An important feature of nanoparticles is that physical properties such as size, surface charge, hydrophobicity, and release charac-

teristics can easily be varied by altering the composition of the formulation and/or the formulation method.

### Lysosomal Targeting

Lysosomal targeting, occurring in many forms of endocytic uptake, has shown an application in therapy of lysosomal storage diseases, including exogenous delivery of enzymes (or genes), such as glucocerebrosidase, fucosidases, phenylalanine ammonia lyases, and others (Sands and Davidson, 2006).

### Cytoplasmic Targeting

Nanoparticles are able to escape the endolysosomes depends on the surface charge of the nanoparticles (Panyam and Labhasetwar, 2004). Nanoparticles that show transition in their surface charge from anionic (at pH 7) to cationic in the acidic endosomal pH (pH 4–5) were found to escape the endosomal compartment, whereas the nanoparticles that remain negatively charged at pH 4 were retained, mostly in the endosomal compartment (Panyam *et al.*, 2003). Thus, by varying the surface charge, one could potentially direct the nanoparticles either to lysosomes or to cytoplasm. Delivery to cytoplasmic targets is of special significance for siRNA delivery.

### Targeting to Cytoskeleton and Caveolae

A special targeting to subsurface structures is that of targeting to cytoskeleton and caveolae. Many diseases have now been associated with abnormalities in cytoskeletal and nucleoskeletal proteins (Ramaekers and Bosman, 2004). Very little has been proposed for such targeting. Targeting drugs to caveolae structures (a subcompartment of the plasma membrane) could potentially interfere with diseases such as muscular dystrophy and cancer, among other diseases (Campbell *et al.*, 2001). Gene delivery to such a compartment is quite open to further exploration.

### Mitochondrial Targeting

It seems possible to localize nanovehicles to mitochondria by modifying the nanoparticle surface to obtain a high net positive charge (Panyam *et al.*, 2002). Delivery to mitochondria has been reviewed (Murphy and Smith, 2000; Holcik, 2004). Permanently positive motifs with delocalized cationic charge, like oligoguaninidines, can target molecules and nanovehicles to mitochondria in response to the highly negative membrane potential (Rothbard *et al.*, 2005). The correction of a mitochondrial deficiency has been demonstrated to be facilitated by this mechanism (Holt *et al.*, 1988).

### Nuclear Targeting

Organelle-specific localization signals, such as fusogenic endosomal membrane peptide or nuclear localization signal (NLS), can be attached to the nanoparticle surface,

enabling nanoparticles to target the nucleus (Simoes *et al.*, 1998). Nuclear targeting is of eminent significance for traditional gene delivery.

### Tissue Localization

Targeted delivery of therapeutic agents to specific tissues has been made feasible due to a number of developments, such as monoclonal antibodies, discovery of specific receptors that are either overexpressed or expressed only in specific tissues, and development of conjugation techniques to attach antibodies or ligands to drug delivery systems. Targeted delivery results in higher bioavailability of the therapeutic agent at its site of action and at the same time results in reduced side effects. Several methodologies have been developed to enable tumor-specific drug delivery.

### Specificity of Targeting

The development of nanovehicular delivery systems for targeted delivery has been reviewed recently by Moghimi *et al.* (2005). Active targeting of a therapeutic agent or a carrier is achieved by conjugating the therapeutic agent or the carrier to a tissue- or cell-specific ligand (Cegnar *et al.*, 2005). Passive targeting is achieved by coupling the therapeutic agent to a macromolecule or carrier that passively reaches the target organ (Nori and Kopecek, 2005). Nanoparticles can be passively targeted to the RES system and circulating macrophages. According to Senger's findings (Senger *et al.*, 1983), polymeric drugs (and gene vectors) accumulate in tumor tissue at 5–10 times greater concentrations in the 24 h after intravenous injection. Ideally, the nanovector size should not exceed 300 nm for optimum transport to tumor sites (Green *et al.*, 1998). Such sizes above a critical 300 nm are also most vulnerable to macrophage phagocytosis.

Only a few successful examples of targeting are accompanied by details on their mechanism. With regulatory approvals of drugs such as Herceptin (trastuzumab), for the treatment of metastatic breast cancer, and Gleevec (imatinib mesylate), for the treatment of chronic myelogenous leukemia, a new class of therapeutics, based on selective drug (gene) targeting to pathologic components, has been clinically validated. Within this growing class of targeted pharmaceuticals, folate–drug conjugates constitute a well-studied example of a distinct subclass of receptor-targeted therapeutics. Folic acid selectively binds to and delivers attached drugs and genes into any cell that expresses a cell surface folate receptor (FR). Because FR is expressed and accessible primarily on pathologic cells, folate conjugation allows delivery of nonspecific drugs selectively into pathologic cells. As a consequence, normal tissues lacking FR are spared the toxicity that commonly limits nontargeted therapies (Hilgenbrink and Low, 2005).

Targeting with help of transferrin represents another example. Iron-transporting protein (Trf) is up-regulated in tumor cells. DNA/lipid-based liposomes, coated with anti-

transferrin receptor single-chain antibody fragment and PEG, lead to an efficient delivery to tumors, inhibiting the first-pass clearance observed with non-PEG-containing liposomes (Yu *et al.*, 2004). Specific targeting of genes by means of many different ligands has been readily used to guide gene delivery.

### Tumor Targeting

Gene delivery to cancer represents about two-thirds of present clinical trials. Targeting to the tumor vascular compartment provides improved cancer therapy. The advantages of targeting tumor vasculature are numerous (Alessi *et al.*, 2004):

- Better selectivity of the treatment against proliferative tumor-derived endothelial cells and minimal toxicity because angiogenesis in the adult is limited to wound healing, ovulation, and pregnancy.
- Easy access for drugs from the blood to tumor vascular endothelial cells (compared with drugs that have to penetrate large, bulky tumor masses).
- Low mutation rate (high, genetic stability of host endothelial and stromal cells) within the vasculature, and thus treatment is independent of tumor-cell resistance mechanisms.
- Broad applicability (both solid tumors and leukemia are dependent on angiogenesis for their survival) and high efficacy because each tumor capillary supplies hundreds of tumor cells.

There are some concerns on the development of resistance. To overcome different modes of resistance, broad-spectrum antiangiogenic modalities should be used or, alternatively, a combination of antiangiogenic agents or a combination of an antiangiogenic agent with drugs (or genes) that decrease the survival threshold of the tumor vascular compartment could be considered.

While considering endothelium as a target, we should differentiate between the endothelium as a portal for delivery vs. destruction of tumor vasculature. While attempting the latter, one should point out that avascularity of tumor (or of its regions) often translates into limited drug delivery to tumors (Baish *et al.*, 1996) because poorly vascularized portions of tumor will accumulate fewer drugs and genes.

## VII. DRUG LOADING

Nanovector cores serve as a reservoir for releasing and delivering drugs and genes. However, the small internal cavity or extravehicular surface does not permit high drug loading. For example, dendrimer-based nanovehicles, due to their small size, have a poor capacity to incorporate active compounds. Thus the delivery application is limited to very potent drugs (biological modifiers), such as peptides, gene vectors, oligonucleotides, antibody fragments, and cytokines. The capacity of a nanovehicle is determined primarily by the chemistry of the vehicle, of both the core and the surface. Polymeric vehicles are promising drug carriers, of

which the critical parameters, such as size and drug loading and release, can be controlled by engineering the constituent polymers. As a rule, the core chemistry controls the drug loading (and release). A hydrophilic core is amenable to charged drugs and noncharged entities. Unfortunately, no systematic research is available to assess the drug loading as related to polymeric carrier chemistry. Most gene agents are hydrophilic and are typically associated with hydrophilic core polymers of nanovehicles or the inner hydrophilic cavity of certain liposomes.

## VIII. GENE DELIVERY SYSTEMS (GDS)

The ideal nanoparticle vector would achieve a long circulation time, a low immunogenicity, a good biocompatibility, selective localization, efficient penetration of physiological barriers such as vascular endothelium and the blood–brain barrier, external activation or self-regulating drug release, and have no clinical side effects. Universal tools, such as PEGylation and “antibody decoration,” become requisite features to improve circulation time and enable selective targeting. In many delivery systems the gene vector or viral particle is entrapped within the core of the generated nanovehicle. The one exception is gene delivery based on condensed gene vectors with the help of cationically charged polymers.

Because there are many types and approaches, with many modifications and modalities, we will be able to list only a few examples of the concrete chemistry for gene delivery. In particular, we may describe some surface modifications that enable one to engineer a stealth character or to provide a targeting capability. A convenient summary is reported in Tables 35.2 and 35.3, listing examples of applications and of marketed gene nanovehicular products. Figure 35.3 demonstrates typical size ranges of different nanovehicular types. Sizes may be outside of the optimal range for given application. However, the present available data do not allow a solid generalization. The same applies to a selection/choice of a particular nanovehicular carrier and its specific application, while some guidance is provided with cited examples.

## Nanoparticles

### PLGA Nanoparticles

Aliphatic poly( $\alpha$ -hydroxy ester)s, such as poly(L-lactic acid) [PLA], poly(glycolic acid) [PGA], and their copolymers [PLGA], belong to the most widely utilized class of polymers approved for human clinical use. They were among the first

**FIG. 35.3.** Typical range of sizes of several representative classes of nanovehicles. Sizes beyond the 200-nm limit may be too large to enable efficient uptake, both *in vitro* and *in vivo*, and to minimize the RES system.

Hellios™	Gene gun/generic	Bio-Rad Laboratories, Hercules, CA

synthetic, biodegradable polymers to be used clinically (Frazza and Schmitt, 1971) and show compatibility with living tissue. These polymers are commercially available with different molecular weights and copolymer compositions. The degradation time of these polymers in tissue can span from several months to several years, depending on the molecular weight and copolymer ratio (Gilding, 1981; Vert *et al.*, 1994). The first PLA nanoparticles were reported by Bazile *et al.* (1992) and the first PLGA nanoparticles by Venier-Julienne and Benoit (1996). A recent review on PLGA nanoparticles (Bala *et al.*, 2004) covers their potential use as carriers for several classes of drugs and genes. PLGA nanoparticles also has been designed for the site-specific delivery of genes (targeting) and evasion of the RES system.

### Polyalkylcyanoacrylate PACA Nanoparticles

Polyalkylcyanoacrylate nanoparticles seem to be an interesting drug carrier, owing to their size, structure, degradability, and drug sorptive properties. They were first prepared by Couvreur *et al.* (1979). Nanosphere preparation methods based on the polymerization of monomers generally consist in introducing a monomer into an aqueous phase or in dissolving the monomer in a nonsolvent of the polymer. The polymerization reaction in these systems generally occurs in two steps: a nucleation phase followed by a growth phase.

Polyalkylcyanoacrylates have been used for several years as surgical glues and are bioerodible (Lenaerts *et al.*, 1984), which is the most significant advantage of alkylcyanoacrylates over other acrylic derivatives previously used. In contrast to other acrylic derivatives, requiring energy input for the polymerization, alkylcyanoacrylates can be polymerized easily without such a contribution, which is another advantage regarding the stability of the associated drug. These nanospheres are prepared by emulsion polymerization of cyanoacrylic monomers dispersed in an acidic, aqueous phase. The size of the nanospheres obtained is approximately 200 nm, but it can be reduced to 30–40 nm using a nonionic surfactant in the polymerization medium. A drug can be incorporated by adsorption or added to the reaction mixture before the polymerization. Lambert *et al.* (2005) reported on oligonucleotide (ODN) delivery with PACA nanoparticles. ODNs entrapped within the PACA nanoparticles were shown to be protected against degradation and to penetrate more easily into different types of cells. *In vivo*, PACA nanoparticles were able to efficiently distribute the ODNs to the liver and improve, in mice, the treatment of RAS cells expressing a mutant Ha-ras gene. Pakunlu *et al.* (2006) demonstrated that PEGylated liposomes are capable of penetrating directly into tumor cells after systemic administration *in vivo* and do successfully provide cytoplasmic and nuclear delivery of an encapsulated anticancer drug, doxorubicin (DOX) and antisense oligonucleotides (ASO). Encapsulation of DOX and ASO into liposomes substantially increased their specific activity.

Simultaneous suppression of pump and nonpump resistance dramatically enhanced the ability of DOX to induce apoptosis, leading to higher *in vitro* cytotoxicity and *in vivo* antitumor activity.

### Polyelectrolyte Complex Nanoparticles (PEC)

Nanoparticles can be made by means of a nonstoichiometric mixing of polyelectrolytes of opposite charge (via ionotropic gelation) by spontaneous association. Prokop *et al.* (2002a, 2002b) reported on multicomponent polymeric complexes that are candidates for delivery vehicles of biological molecules such as proteins and drugs. Biocompatible and largely natural polymers can be fabricated into thermodynamically stable nanoparticles insoluble in water and buffered media, in the absence of organic solvents, featuring core-shell morphology. A careful choice of construction materials and the superposition of several interacting principles during PEC production allows for the customization of the physicochemical properties of the structures. A recent development involves low-molecular-weight polymers. Typically, nanoparticles are made by mixing polyanionic core polymers, such as alginate, and chondroitin sulfate, and the corona polycations, such as spermine hydrochloride, and poly(methylene-co-guanidine) hydrochloride (PMCG). PMCG is a synthetic oligomer that mimics peptide structure. It contains highly charged cationic guanidine groups. This multipolymeric nanoparticulate system was shown to be very effective for *in vitro* gene transfer (Carlesso *et al.*, 2003), particularly in cell systems that are normally refractory to gene transfer, such as pancreatic islets and antigen-presenting cells (Fig. 35.4). Recent data revealed that such nanoparticles are taken up by means of a non-specific adsorptive endocytosis and/or via fluid-phase endocytosis.

Alonso *et al.* (Fernandez-Urrusuno, 1999; Calvo *et al.*, 1997) introduced chitosan-based nanoparticles. Chitosan (CS) nanoparticles are obtained by the process of ionotropic gelation based on the interaction between the negative groups of the pentasodium tripolyphosphate (TPP) and the positively charged amino groups of CS. This process has been used to prepare nanoparticles for the delivery of peptides and proteins, insulin, and cyclosporine. A wider application of this product has been prevented by an instability resulting from the ion exchange (followed by dissolution) between the polyions incorporated into the nanoparticle and small ions present in the foregoing environments. However, this system offers an interesting potential for transmucosal delivery. Howard *et al.* (2006) employed chitosan nanoparticles to mediate knockdown of endogenous enhanced green fluorescent protein (eGFP) in both H1299 human lung carcinoma cells and murine peritoneal macrophages (77.9% and 89.3% reduction in eGFP fluorescence, respectively). Effective *in vivo* RNA interference was achieved in bronchiole epithelial cells of transgenic eGFP mice after nasal administration of chitosan/siRNA

**FIG. 35.4.** Nanoparticle-mediated gene transfer into islets. Freshly isolated murine islet cells were transduced with either adenovirus containing NP (NP-AdV, MOI = 10) or free adenovirus (AdV, MOI = 10) in complete growth media. After 16 h, cells were washed twice with PBS and cultured with growth medium. At 24 and 48 h, cells were harvested and assayed for luciferase expression. Luciferase values were normalized on the basis of protein content. Courtesy of ACS.

formulations (37% and 43% reduction as compared to mismatch and untreated control, respectively).

Other powerful PEC gene delivery systems include polyethyleneimine (PEI) (Demeneix and Behr, 2005) and poly-L-lysine (PLL). Many other cationic polymers have been employed and tested.

### Polymeric Micelles

This technology has been pioneered and developed by K. Kataoka in Japan (Kataoka *et al.*, 2001). Polymeric micelles, core-shell type colloidal carriers for drug and gene targeting, prepared from the self-assemblies of block copolymers, are one of the most refined and promising modalities of drug delivery, since the critical parameters, such as size and drug loading and release, can be controlled by engineering the constituent block copolymers. It has been demonstrated that polymeric micelles show unique disposition characteristics in the body, suitable for drug targeting (e.g., prolonged blood circulation and significant tumor accumulation). Novel approaches for the formation of functionalized poly(ethylene glycol) (PEG) layers as an hydrophilic outer shell were developed to attain receptor-mediated drug and gene delivery through PEG-conjugated ligands with minimal nonspecific interaction with other proteins. Oishi *et al.* (2005) demonstrated efficient intracellular *in vitro* siRNA delivery.

### Dendrimers

Dendrimers are attractive macromolecular systems for drug delivery because of their nanometer size range (5–20 nm), ease of preparation and functionalization, and their

ability to display multiple copies of surface groups for biological recognition processes (Morgan and Cloninger, 2002). Dendrimer molecules are monodisperse symmetric macromolecules built around a small molecule or in a linear polymer core using connectors and branching units. Interaction of dendrimer macromolecules with the molecular environment is controlled predominantly by their terminal groups. By modifying their termini, the interior of a dendrimer can be made hydrophilic while its exterior surface is hydrophobic, or vice versa. Dendrimers can be synthesized starting from the central core and working out toward the periphery (divergent synthesis) or in a top-down approach starting from the outermost residues (convergent synthesis). Commonly used and commercially available polyamido-amine dendrimers (PAMAM) form spherical polymers with good aqueous solubility, because of their highly charged exposed surface groups, with abundant primary amines for convenient functionalization (Majoros *et al.*, 2005). PEGylation of amino-terminated PAMAM dendrimers has reduced their immunogenicity, improving lifetime circulation (Bhadra *et al.*, 2003). A high *in vivo* activity, using a luciferase reporter, has been demonstrated with dendrimers (Banerjee *et al.*, 2004).

### Liposomes

Liposomes are small artificial vesicles of spherical shape that can be produced from natural nontoxic phospholipids and cholesterol. Because of their size, hydrophobic and hydrophilic compartments, as well as biocompatibility, liposomes are promising systems for drug delivery. Liposome properties vary substantially with lipid composition, size, surface charge, and the method of preparation. They are therefore grouped into three classes based on their size and the number of bilayers. Small unilamellar vesicles (SUV) are surrounded by a single lipid layer and are 25–50 nm in diameter. Large unilamellar vesicles (LUV) are a heterogeneous group of vesicles similar to SUVs. Multilamellar vesicles (MLV) consist of several lipid layers separated from one another by a layer of aqueous solution. Although SUVs can carry soluble substances in their lipid bilayer structure, MLVs can also carry membrane-bound lipophilic drugs for sustained release. A combination with a cationic lipid results in a cationically charged liposome (lipoplex). Liposomes are of significance for gene delivery because DNA can be incorporated within the aqueous-phase cavity.

Lipofection has been used with a variety of cell types *in vitro* as well as tissues *in vivo*. (Felgner and Ringold, 1989; Li and Hoffman, 1995). The main advantages of liposomes are that there are few constraints to the size of the gene which can be delivered, and liposomes are relatively nontoxic and can be applied repeatedly. A drawback of lipofection is the low frequency of stable transfection. The ability to target these liposome vectors to specific cells is also limited. Recent efforts to target liposomes to specific cell

types have focused on the incorporation of a variety of ligands into the liposome-DNA complex (Trubetskoy, 1992). Several lipid-based nonviral vectors are currently under investigation for gene delivery (Rosenberg *et al.*, 2000).

Liposome shielding from the RES has been achieved by PEGylation (addition of PEG) (Blume and Cevc, 1990; Crosasso *et al.*, 2000; Cattel *et al.*, 2004). Targeting of liposomes has been readily demonstrated (e.g., antibody-conjugated liposomes) (Ishida *et al.*, 1999). Major progress is expected from developments of many different modalities of liposome preparation, including those of pH-sensitive status, cytosolic delivery of siRNA, delivery of cytotoxic agents and toxins, antigen delivery and viral gene delivery systems, and from functionalized liposomes (Drummond *et al.*, 2000). There are numerous commercial formulations for gene delivery.

### Cell-Penetrating Peptides (CPPs)

CPPs are up to 30 amino acid amphiphilic peptides, which can be internalized by cells via mechanisms that require no energy and can be receptor mediated. Protein-derived CPPs usually consist of the minimal effective partial sequence of the parent translocation protein and are also known as protein transduction domains or membrane translocation sequences (Zorko and Langel, 2005). CPPs from different classes do not share common amino acid sequence motifs. The only two common features of all CPPs appear to be a positive charge and amphipathicity.

Protein transduction occurs by a rapid, lipid raft-mediated macropinocytosis mechanism that is independent of receptors and transporters that all cells perform. Typically, an efficient cytoplasmic delivery occurs (Oehlke *et al.*, 2005). This is based on observations with an inhibition of this uptake by negatively charged GAG molecules (glycosaminoglycans, HSPG), dextran sulfate and heparin. This is supported by observations on inhibition of CPP uptake in GAG-deficient cells (Marty *et al.*, 2004).

CPPs do not belong to nanovehicles. These are listed here because such motifs are often used to functionalize nanovehicles in order to enable their uptake and quick penetration. It is implied that the mechanism of uptake of such vehicles may be similar to those of plain CPPs. Such nanovehicle functionalization is expected to play a significant role in future in gene delivery (Turner *et al.*, 2006).

### Special Generic Systems

Several inorganic systems have been reported for drug and gene delivery. These include calcium phosphate, nanogold, carbon material, silicon oxide, and iron oxide (Martin and Kohli, 2003; Kam *et al.*, 2005; Jain *et al.*, 2005; Maitra, 2005; Gemeinhart *et al.*, 2005). Carbon nanotubes are one-dimensional tubular objects of carbon that can be either multiwalled or single-walled. In addition, they can be functionalized, permitting an attachment of ligands and drugs (Klumpp *et al.*, 2005).

## IX. SPECIAL CONSIDERATIONS FOR GENE DELIVERY SYSTEMS

These vehicles comprise nonviral and viral systems. Nonviral gene delivery refers to the use of naked DNA, biolistic delivery, cationic lipids formulated into liposomes and complexed with DNA (lipoplexes), cationic polymers complexed with DNA (polyplexes), polymeric vesicles complexed with DNA (cholesterol vesicles), polymeric nanoparticles, or a combination of both cationic lipids and cationic polymers complexed with DNA (lipoplexes, Lipofectamine™). Many different chemistries and modifications were introduced earlier; some are special to gene delivery. Nonviral systems are treated first. This distinction has been introduced because differences in the outcome of gene expression are still quite great: Nonviral systems are still quite inefficient. A common feature is the nature of forces involved in the gene agent entrapment: In many of the formulations certain electrostatic forces predominate, as opposed to the many different mechanisms involved in generic nanovehicle assembly. For the former systems, the stability of such complexes is of crucial importance for *in vitro* and *in vivo* applications, as reviewed earlier. Surveys of the distinct advantages and disadvantages of gene delivery systems are available (Eming *et al.*, 2004).

### Nonviral Systems

Rapid advances have been made in the development of more physiological means (nonviral) to introduce genes into target cells. Nonviral gene transfer systems have the advantage of delivering genes to target cells without the inherent disadvantages of viral-based systems, such as antigenicity, potential for recombination with wild-type viruses, and possible cellular damage due to persistence or repeated exposure to the viral vectors (Felgner and Rhodes, 1991). These synthetic systems are also easier to manufacture on a large scale because they typically use plasmid constructs that can be grown with existing fermentation technology. Direct plasmid application, lipofection, and receptor-mediated delivery vectors are the most promising nonviral systems. Other nonviral transfection techniques are too inefficient for clinical use (i.e., electroporation, microinjection of DNA).

Typical nonviral gene delivery payload agents include gene vectors and therapeutic oligonucleotides, antisense, ribozymes, DNAzymes, aptamers, and small interfering RNAs — siRNAs. Selective silencing of genes was initially accomplished with short antisense oligonucleotides, pieces of DNA that hybridize with the target mRNA and inhibit their translation into the protein. A clinical trial is ongoing targeting of certain genes involved in oncogenesis (Stephens and Rivers, 2003). Specifically, in this case, oligonucleotides, sensitive to enzymatic breakdown, were replaced by derivatives, with the phosphorothioate backbone in place of original phosphoester backbone. Ribozymes are naturally occurring enzymes consisting of RNA, resulting in cleaving

of RNA. A down-regulation of oncogenes resulting in tumor suppression has been reported (Ala-aho *et al.*, 2004). Deoxy-ribozymes or DNAzymes (enzymes made of DNA) are artificial molecules and are not found in nature. Silverman (2005) has isolated a multitude of DNAzymes that catalyze RNA ligation. RNA-cleaving DNAzymes, DNAzymes able to catalyze RNA hydrolysis in the absence of divalent metal ions, have been discovered. Aptamers are synthetic RNA molecules capable of capturing ligands with high binding selectivities and affinities for a specific target. They have proven to be valuable therapeutic agents with enhanced properties relative to antibodies (Nimjee *et al.*, 2005). Short interfering RNAs serve for a specific knockdown of genes. Sumimoto *et al.* (2004) demonstrated an *in vivo* melanoma inhibition with lentiviral vector encoding for siRNA directed against the mutated oncogene BRAF. While plasmid DNA needs to enter the nucleus, siRNA and other carriers mentioned earlier need only to reach the cytoplasm, since they act by mRNA degradation.

One of the most practical methods for delivering the DNA to the target tissue is the *direct injection* of DNA into the tissue. This approach was first investigated by Hengge and coworkers, who demonstrated that DNA injected directly into the skin can be taken up by keratinocytes, and its transient expression can induce a biological response (Hengge *et al.*, 1995). The efficacy of this approach has now been supported by reports of other groups (Sun *et al.*, 1997; Meuli *et al.*, 2001; Sawamura *et al.*, 2002). A more sophisticated technique for the delivery of naked DNA has been described by Ciernik *et al.* (1996) and Eriksson *et al.* (1998) and is named *puncture-mediated gene transfer* or *microseeding*, respectively. These techniques deliver the DNA directly to target cells by multiple perforations using oscillating solid microneedles. The authors state that transgene expression by microseeding is more efficient than delivering DNA by a single dermal injection.

Commonly used polymers include PEI, PLL, chitosans, and dendrimers. Nonviral vectors are receiving increasing attention due to compound stability, potential ease of chemical modification, low cost and consistent standard of production, and higher biosafety and flexibility (Dyer and Herrling, 2000). The cationic polymers usually bear protonable amines, enabling their complexation with nucleic acids and securing their transfection efficiency. Due to electrostatic interactions between the positively charged amino groups and negatively charged phosphate groups of plasmid DNA, polycations spontaneously form complexes with a display of rapid condensation. The ratio of polycation/DNA then allows for a charge control. Aggregation of originally colloidal structures (although of different submicroscopic shape) is one of the problems. Similarly, *in vivo*, biological fluids often cause an aggregation when complexes are introduced. Recent data suggest that coating the polycation/DNA complexes with polyanions can diminish particle aggregation (increasing colloidal stability) (Trubetsky *et al.*, 2003).

Some targeting of gene complexes with suitable ligands has been achieved (e.g., Sagara and Kim, 2002).

Besides polycations, other polymers were suggested to condense large genes into smaller structures and to mask negative DNA charges. They include neutral polyvinyl alcohol, polyvinylpyrrolidone, and PEG copolymers. Many different polymeric approaches were summarized by Piskin *et al.* (2004).

Different nanoparticulate formulations have been shown to transfer genes in a significantly higher portion as compared to naked DNA (e.g., Hass *et al.*, 2005) but much less than the viral systems. Carlesso *et al.* (2003) have demonstrated highly efficient, nanoparticle (PEC)-based gene delivery *in vitro* and *in vivo*.

Biolistic method uses the handheld gene gun with a pulse of helium to fire small gold particles coated with DNA at target cells. This method of biolistic transfection is becoming increasingly popular as an effective means of rapid gene delivery into mammalian tissue. It is restricted to local expression in the dermis, muscle, or mucosal tissue. Current methods of microcarrier preparation, however, are slow (up to two days) and can result in variations in transfection efficiency due to a number of problems, including shearing of DNA, agglomeration, and adhesion of gold particles. One of the major applications of the gene gun is genetic vaccination in the form of intramuscular or cutaneous injection of DNA (Nanney *et al.*, 2000).

Nonviral gene transfer systems have the advantage of delivering genes to target cells without the inherent disadvantages possessed by viral-based systems (see later), such as antigenicity, potential for recombination with wild-type viruses, and possible cellular damage due to persistence or repeated exposure to the viral vectors (Eming *et al.*, 2004). Lipofection, and receptor-mediated delivery vectors (e.g., ligand-modified PEI–DNA complex) are the most promising nonviral systems. Ogris *et al.* (2003) demonstrated 10–100 times higher reporter gene expression (pCMVLuc) by employing Trf or an EGF-decorated PEI–PEG–liposomal delivery system in mice tumors. For RGD-decorated liposome-protamine DNA formulation, Harvie *et al.* (2003) showed 100-fold enhancement of transfection activity in tumor cells overexpressing appropriate integrin receptor *in vitro*, while Hofland *et al.* (2002) achieved a 50- to 100-fold reduction in RES tissue (lungs) while using folate-targeted liposomes as compared to nontargeted liposomes; however, the accumulation of complexes and gene transfer activity was not altered.

## Viral Systems

Having evolved to deliver their genes to target cells, viruses are currently the most effective means of gene delivery and can be manipulated to express therapeutic genes or to replicate specifically in certain cells. Gene therapy with attenuated viruses is being developed for a range of diseases, including inherited monogenic disorders and cardio-

vascular disease. But it is in the treatment of cancer that this approach has been most evident, resulting in the recent licensing in China of a gene therapy for the routine treatment of head and neck cancer. A variety of virus vectors have been employed to deliver genes to cells to provide either transient (e.g., adenovirus, vaccinia virus) or permanent (e.g., retrovirus, adeno-associated virus) transgene expression, and each approach has its own advantages and disadvantages (Eming *et al.*, 2004).

Adenoviruses (AdV) are the most commonly used therapeutic models, where mechanisms for initial fiber protein binding with CAR cell surface receptors (followed by endocytosis) have been actively investigated for tissue and organ targeting in human gene therapy (Roelvink *et al.*, 1999). The AdV vectors remain in an extrachromosomal location and are replication-defective, resulting in transient expression. AdV vector has an outstanding capability of escaping from endosome to cytoplasm and passing through the nuclear pore membrane. Despite extensive investigation of dozens of viral vectors for cancer treatment and promising results in clinical trials, the FDA has not approved any virus-based therapeutics because of toxicities and immunogenicities widely reported in gene therapy (Lin and Nemumaitis, 2004).

To date, adenoviral vectors have demonstrated the highest gene transfer efficiency *in vivo* (Wilson, 1996). Unlike retroviruses, adenoviruses can easily be concentrated to high viral titers and can infect dividing as well as nondividing cells with high efficiency. This is a major advantage for some applications, including gene transfer to the lung, where cell division is infrequent. A major drawback in the use of adenoviral vectors is the cytotoxicity of viral proteins and the host cellular immune response to the adenoviral proteins of the virus particle, which results in local inflammation and destruction of transduced cells.

Adeno-associated viruses are small nonenveloped viruses, which are not known to cause any human disease (Levine and Friedmann, 1993). The adeno-associated virus can transduce a wide range of dividing and nondividing cells, but its main advantage is that it integrates reliably into a specific position on chromosome 19, which reduces the probability of inadvertent activation of a protooncogene (Levine and Friedmann, 1993; Monahan and Samulski, 2000). The disadvantages of adeno-associated viruses are that the vector packages only small transgenes (up to 4.7 kbp), and the preparation of the recombinant vector is frequently contaminated with wild-type adenovirus, which must be separated or inactivated.

The major advantages of retroviral-mediated gene transfer are that recombinant retroviruses are capable of transferring genes to a wide range of different cell types, including normal diploid cells, the genes are stably integrated into the chromosomal DNA at relatively high frequency, without rearrangements, and retroviruses are capable of transferring genes simultaneously to large numbers of cells at high effi-

ciencies. The disadvantage of retroviral-mediated gene transfer is that a gene of only limited size (<6 kbp) can be packaged and transferred. Integration of the transferred gene is dependent on cell division, which limits the types of cells and tissues that can be modified. Although long-term gene expression has been reported in some systems, including fibroblasts and muscle cells, transient expression in retrovirally modified cells has also been described (Palmer *et al.*, 1991; Roemer and Friedmann, 1992).

Herpes simplex virus type-1 (HSV-1) is a human neurotropic virus used primarily as a vector for gene transfer to the nervous system, although the wild-type HSV-1 can infect and lyse other nonneuronal epithelial cells. Because of its large genome size, up to a 30–50-kbp transgene can be packaged into recombinant HSV-1 vectors. At present, two major classes of HSV-1 vectors have been developed: replication-defective viruses and replication-conditional mutants (Roizman, 1996; Glorioso *et al.*, 1997). However, the ability of HSV and these mutant recombinants to establish lifelong latent infections raises concerns about the use of these vectors in humans. Efforts have been made to create HSV-1 amplicon vectors essentially free of HSV-1 helper virus, which might be a promising genetic vehicle for *in vivo* gene delivery (Costantini *et al.*, 2000).

### Targeting and Retargeting Modalities

Recently, Bazan-Peregrino *et al.* (2006) reviewed current therapeutic modalities and transductional and transcriptional detargeting and retargeting strategies for gene delivery of both nonviral and viral systems to tumor vasculature. The conclusions are of general significance. Transductional targeting is achieved by employing small peptides or antibodies attached to the viral particles genetically or chemically (by means of reactive bifunctional reagents) in order to eliminate their normal tropism and potentially introducing new ones. Transcriptional targeting can be achieved by placing the transgenes under the control of tumor vasculature-associated promoters (e.g., hypoxia-responsive, vascular endothelial growth factor, adhesion molecule, and other endothelial cell-specific promoters). A combination of transductional and transcriptional targeting is also possible. Specific examples are listed in the original review as well as those of antiangiogenic gene therapy targeted to nonendothelial or stem cells. The identification of promising new targets (e.g., pericytes, smooth muscle cells, tumor stroma) for molecular interventions using gene therapy will eventually lead to a combination therapy of these new treatment modalities.

## X. OUTLOOK

Nanovehicles loaded with an appropriate drug or gene offer improved spatiotemporal control (window) over drug kinetics and distribution. It should be restated that the ratio of the amount of drug released from nanovehicles within the bloodstream to the amount taken up intracellularly is

governed by the circulatory properties of vehicles in the central compartment, by the release rate from nanovehicles in this compartment, and by the efficiency of intracellular uptake, no matter what the mechanism of uptake. This is the nanovehicular ratio of systemic to intracellular localization (S/I ratio). In order to optimize this ratio, one should maximize the circulation time and release and minimize the uptake. In other instances, intracellular delivery is desirable. Thus, there is a prospect for safer and mode-specific treatment therapies.

In the coming years, we expect vigorous progress on the cell and molecular biology sides, which will further enhance our understanding of the basic phenomena involved in drug/gene/vehicle uptake. Internalization of the delivery systems results in a poorly defined trafficking process. Elucidation of the nonendocytic pathway(s) mechanism may help the creation of rationally designed vehicles. The uptake of nanovehicles is a rather understudied area, even though a lot of similarities and ideas come from the area of the uptake of macromolecules. However, there may not be a single specific uptake pathway responsible for intracellular delivery. A series of inhibiting agents with preferably different modes of inhibition should be applied and combined with colocalization studies. Besides, it is not clear how the macromolecular properties of nanovector, particle size, sterical stabilization, and the specific design of homing devices as well as the cargo chemistry influence the mechanism of uptake. Such diversity in the nanovehicle uptake mechanisms employed by each cell type then offers the possibility

of manipulating and enhancing the uptake via the desired route (Huth *et al.*, 2006).

The adjustable size of nanovehicles to a rather narrow-sized window determined by the size of blood vessels (both by the upper and lower limits of normal and pathological vasculature) and epithelial barrier openings in the case of oral applications and the opportunity of targeting preclude other delivery vehicles from gaining a strong foothold in future applications. In all cases, safety and economic considerations will control the ultimate application and its success.

A considerable research dilemma is the selection/choice of a suitable nanovehicular delivery vehicle for a specific application. Individual authors tend to prefer their own vehicle, and no generalizations or rules of thumb are available to guide the selection. The desirable delivery route and localization and biocompatibility of nanovehicles will, in the end, dictate the utility of individual constructs.

Because of the rather steep cost for preclinical toxicology testing of novel delivery vehicles, the pace of implementation of new delivery modes will not be high. Other considerations, such as patent expiration, may help drive the introduction of new or reformulated drug entities and place them on the market. Besides, large-scale manufacturing is most critical. Residual solvents where solvent-based methods are used to manufacture nanovehicles must be minimized via a complete evaporation in the final preparation. The nanoscale-based delivery strategies are beginning to make significant inroads on the global pharmaceutical industry.

## XI. ACKNOWLEDGMENT

We acknowledge the support of the National Institutes of Health Grant 1R01EB002825-01 (J.M.D. and A.P.) and support from the Department of Veterans Affairs (J.M.D.).

### I. INTRODUCTION

Reconstructive surgery after mastectomy or lumpectomy due to breast cancer may benefit greatly from tissue engineering for the creation of new soft-tissue replacements. Various cell types can be used for breast reconstruction, including preadipocytes, fibroblasts, smooth muscle cells, muscle myocytes, and chondrocytes. To introduce a cell-polymer construct into the body, proper selection of the polymeric materials should provide three-dimensional support for engineered new tissue. There are two strategies for introducing the cell-polymer constructs into the body. The first is to implant surgically, while the second approach is to deliver in a minimally invasive manner using injectable forms of materials. A critical challenge to engineer large tissue masses is vascularization, and approaches to optimize this process include delivery of angiogenic molecules or endothelial cells.

According to the American Cancer Society, approximately 182,000 new cases of breast cancer are detected each year that can potentially require breast reconstruction. Breast cancer represents the second most common cancer in the female population. In the United States approximately one out of every eight women will develop the disease (American Cancer Society, 2006), and it is the second leading cause of cancer-related death in women. Approximately \$8.1 billion is spent each year in the United States for breast cancer treatment. Historically, breast cancer was treated

with radical mastectomy. Radical breast surgery was developed at a time when breast cancer was typically very large and was often unresectable by then-current standards. This procedure removed the breast, underlying pectoral muscles, and axillary lymph nodes. The surgical treatment of breast cancer has expanded from the traditional radical mastectomy. Radical mastectomy gave way to modified radical mastectomy. Advances in cancer detection and increased awareness through self-examination have allowed cancers to be discovered at early stages. Small lesions can now be treated with lumpectomy (removal of the part of the breast containing the tumor plus some surrounding nontumor-bearing tissue) along with radiation. Axillary lymph node metastasis can be evaluated through sentinel lymph node biopsy, avoiding the morbidity of a full axillary dissection. Randomized prospective clinical trials conducted during the past 30 years comparing these less deformative techniques have demonstrated survival rates equivalent to those for modified radical mastectomy (Lichter, 1997). These studies have demonstrated unequivocally that for most women with small breast cancers, simple excision (lumpectomy) of the breast cancer with sampling of the axillary lymph nodes followed by radiation provides an outcome similar to that for radical mastectomy. However, in some women mastectomy remains the best treatment, due to extensive tumor involvement within the breast, which requires removal of all or most of the breast tissue.

The current approaches to reconstructing breast tissue following a mastectomy include reconstructive surgery utilizing autologous tissue flaps or implants of synthetic materials. Complex flap reconstruction using transversus rectus abdominal myocutaneous (TRAM) flaps, latissimus dorsi flaps, or muscle-free flaps from the buttock or thigh are used to reconstruct large volumes of lost breast tissue. These are very extensive procedures with long recovery periods, and they require the harvest of tissue from another site in the body, with its attendant side effects and complications. The advantage of this approach is that a patient's own tissues are utilized, resulting in a more natural tactile tissue quality. Grafting of autologous fat is another technique that has been utilized for reconstruction. The procedure produces poor results, for several reasons. The cellular material used for transplantation is obtained from lipoaspiration, a process that can damage and lyse the cells. Second, the transplanted cells consist mainly of adipocytes that are terminally differentiated and incapable of proliferation (Patrick, 2004). A more common procedure involves the use of synthetic materials. In this process a tissue expander is placed, usually beneath the pectoral muscles, and gradually inflated over several weeks to the desired size. It is subsequently removed by a relatively simple procedure, and a saline-filled permanent silastic implant is placed into the cavity. Because the implant is a foreign body, there may be a substantial inflammatory response producing fibrosis, thickening, and an unnatural shape and tactile quality. Also, implants may leak and require replacement. Silicone-filled implants are now rarely used, due to fears of a possible induction of autoimmune disease caused by the leakage of silicone. These reconstructive approaches have been designed for the mastectomy procedure, and currently there is no reconstructive option for patients who are candidates for a lumpectomy procedure.

Tissue engineering is potentially a potent approach to treating the loss of tissues or organs (Langer and Vacanti, 1993; Mooney and Mikos, 1999), and it could find wide utility in breast-tissue reconstruction. There are myriad potential indications to apply tissue engineering for tissue reconstruction, including postoncologic resection (i.e., mastectomy, lumpectomy, and parotidectomy), soft-tissue defect from trauma, and congenital defects. Engineered breast reconstruction can be approached through one of two basic pathways: either *in situ* adipogenesis or *de novo* adipogenesis. The first technique employs the transplantation of a supportive matrix to encourage the development of adipose tissue *in situ*. The matrix is supplemented with specific growth factors that attract native cells, such as fibroblasts and preadipocytes, to migrate into the matrix (Patel and Patrick, 2004).

*De novo* adipogenesis takes on a slightly different method. In this approach, tissue-specific cells are isolated from a small tissue biopsy and expanded *in vitro*. The cells are subsequently placed onto polymeric scaffolds that act as synthetic extracellular matrices. These scaffolds deliver the cells to the desired site in the body, define a space for tissue formation, and potentially control the structure and function of the engineered tissue (Eiselt *et al.*, 1998; Kim and Mooney, 1998a; Putnam and Mooney, 1996). Utilization of biodegradable polymer scaffolds leads ultimately to a new tissue mass with no permanent synthetic element. New soft tissues, which can be transplanted into a patient to reconstruct lost breast tissue, can potentially be created with this process (Fig. 36.1). This approach may circumvent the main limitations of reconstruction of breast tissue using tissue transplantation while eliminating the need for the permanent implantation of synthetic prosthetic materials.

**FIG. 36.1.** Schematic of the approach to engineer a soft-tissue replacement for women with breast cancer. The first steps include identification and removal of the breast tissue and then isolation and multiplication *in vitro* of appropriate cells derived from another site in the body. These cells are then combined with a biodegradable polymer matrix and implanted in the body to re-create a soft tissue that emulates the lost breast tissue.

In this chapter, we summarize the various cell types that may be useful for breast reconstruction, the polymers that can potentially be utilized in this tissue-engineering approach, and the development of suitable animal models that allow one to test this concept for breast reconstruction. In addition, we review approaches being developed to promote vascularization of the engineered tissue, for this will be a critical challenge to engineering a large mass of soft tissue using a cell transplantation approach.

## II. CELL TYPES FOR SOFT-TISSUE ENGINEERING

Many considerations must be addressed when choosing which cell type(s) should be used in human-breast-tissue engineering. The first consideration is that there be substantial variability in the size, shape, and consistency of the breast. All three factors change over time, with a tendency for breast parenchyma (glands and ducts) to involute or regress as a woman ages, particularly after menopause, and to be replaced by fat. Also, comparing breast tissue among women of any given age, we find considerable variability in size and shape, and tactile, elastic, and tensile characteristics of the tissue. The tensile and elastic characteristics of the breast are produced by three major factors:

1. The amount and quality of fat within the breast.
2. The amount and quality of glandular and duct tissue in the breast.
3. The mechanical characteristics of the fibrous support structures of the breast (Cooper's ligaments).

In breast reconstruction, the creation of a functional breast with lactational ability is not needed and, in fact, may add to a woman's breast cancer risk by introducing mammary epithelial cells that may be predisposed to cancer development. The major goal of breast reconstruction is to produce a breast mound with all of the aesthetic properties of a normal breast. A major concern for a woman undergoing breast reconstruction for cancer or augmentation is that the right side match the left side and that the reconstruction be aesthetically correct. Also, it is important to understand that there is considerable variability in the expectations of women who undergo reconstructive or augmentation breast surgery in terms of the desired size and shape and with the elastic and tactile qualities of the breast reconstruction. With these observations, a projection can be made that fat cells would need to be a major part of the tissue-engineered construct and that other cell types (e.g., muscle) would be needed to contribute appropriate conformational, tensile, elastic, and tactile characteristics of the construct. Also, due to the variability in normal breast, some individual manipulation of these constituents may be required.

A major cell type comprising normal breast tissue, and likely the engineered replacement, is the adipocyte. Lipid-laden fat cells (adipocytes) are terminally differentiated and will not divide further *in vivo* or under cell culture condi-

tions. If these cells were to be used, they would have to be harvested from fat in an equivalent volume required for the construct (Hang-Fu *et al.*, 1995; Kononas *et al.*, 1993; Nguyen *et al.*, 1990). Alternatively, preadipocytes could be used for engineering soft tissue (Coleman *et al.*, 2000; Patrick *et al.*, 1999) because these cells potentially can be expanded in culture. Preadipocytes are similar to fibroblasts in structure and possess the ability to expand in culture. Several studies have shown ways to induce differentiation into adipocytes. These cells can be successfully harvested and isolated from such sites as the subcutaneous tissues and the omentum. Investigations of autologous preadipocyte implantation with a sheep animal model have been promising (Halberstadt *et al.*, 2002). Technologies are being developed that may allow for simple harvesting and fast isolation of preadipocyte cells for immediate reimplantation into the patient to serve as stem cells (Fraser *et al.*, 2006).

Since breast tissue is more than fat alone in most cases, additional cell types must be considered to contribute to the shape and the tactile, elastic, and tensile characteristics of a breast reconstructed via tissue-engineering methods. Possible other cell types include smooth muscle cells, fibroblasts, skeletal muscle, and elastic cartilage. Fibroblasts contribute greatly to the support structure of the breast by laying down bands of collagen that connect the breast tissue to the skin and to the pectoral muscle as well as helping maintain the overall shape. Fibroblasts are an integral component of tissue-engineered skin products, and transplantation of fibroblast-containing tissues has been demonstrated to replace lost skin tissue successfully in several situations (Eagleson and Falanga, 1998; Landeen *et al.*, 1993, 1992; Naughton *et al.*, 1997; Naughton, 2002). The density and firmness of the breast are primary effects of the glandular epithelium and ductal structure. Tissues that have similar tactile and elastic properties are almost exclusively muscle. Smooth muscle cells can readily be isolated from a number of organs and expanded in culture. Techniques have been developed to seed these cells efficiently onto three-dimensional scaffolds fabricated from various polymers (Kim *et al.*, 1998) and to grow new tissues from these cell-polymer constructs with a defined size and shape (Kim and Mooney, 1998b). Implantation of smooth muscle containing polymers can lead to the reformation of significant tissue masses, with reorganization of the smooth muscle tissue into appropriate three-dimensional structures (Oberpenning *et al.*, 1999). Muscle myocytes can also be greatly expanded *in vitro* and have been demonstrated to reform functional tissue masses under appropriate conditions (Vandenburgh and Kaufman, 1979; Vandenburgh *et al.*, 1991). However, it remains to be demonstrated that smooth or skeletal muscle myocytes will maintain a tissue mass over long periods of time without neural stimulation. An alternative approach is to utilize chondrocytes as a component of an engineered breast tissue. Elastic cartilage has many of the mechanical properties of glandular breast tissue that are potentially important for tissue engi-

neering of breast (e.g., elasticity). Chondrocytes can be expanded in culture, and they are able to survive in low oxygen tensions. Chondrocytes have been used extensively in tissue engineering to engineer a variety of tissue constructs both *in vitro* and *in vivo* (Atala *et al.*, 1994; Breinan *et al.*, 1998; Wakitani *et al.*, 1998).

Other cell types, such as mesenchymal stem cells and embryonic stem cells, may be a viable source for breast-tissue engineering. However, in the case of embryonic stem cells, a great deal of work will need to be done to create terminally differentiated cells that, once transplanted, do not have the potential to form a tumor mass. The implantation of embryonic stem cells has demonstrated the potential of forming teratomas *in vivo* (J. A. Thomson *et al.*, 1998; Wobus and Boheler, 2005).

A number of issues must be ultimately addressed in relation to cell expansion for breast-tissue reconstruction. In considering the number of cell types that may potentially be used, it is very likely that a variety of growth factors will be needed for the *in vitro* expansion of cells. Implantable cell-bearing polymers will also need to be created to provide the short- or long-term stimulation of growth factors and other substances to enhance vascularization or to provide or sustain a local milieu that will maintain a stable, healthy tissue mass in an area that may be foreign to the tissue (Mooney *et al.*, 1996b; Peters *et al.*, 1999b; Sheridan *et al.*, 2000). Standard isolation and expansion protocols must also be developed, and critical factors for successful outcomes will include aseptic technique in the harvest, routine quality control testing of all cultures, and long-term cell storage. It may also be possible to isolate all the cell types required for breast-tissue engineering from a single tissue source. For example, fat, in addition to adipocytes, contains a large vascular network, composed primarily of capillary endothelial cells and some vascular smooth muscle cells as well as a collagen stromal structure produced by fibroblasts (Williams *et al.*, 1994). Hence, multiple cell types can potentially be obtained from this tissue. In attempting to produce fat tissue *in vivo*, it may be beneficial to purify and expand the cellular components of fat without isolating each component. This may be particularly important if, as suggested by several authors, vascular endothelial cells and others exhibit organ specificity (Bassenge, 1996; Craig *et al.*, 1998; Murphy *et al.*, 1998).

### III. MATERIALS

Several key characteristics make a biomaterial suitable for tissue engineering. First, favorable biomaterials must be biodegradable and resorb over time. The shape and texture of the material must resemble that of natural tissue. For the purpose of re-creating adipose tissue, the material must have a soft, pliable texture. Cellular adherence is another important aspect of any potential material. The biomaterial must interact favorably with its cellular components without negatively impacting them (the material cannot be tumori-

genic). A porous surface is another key feature that potentially allows for cellular ingrowth into the material, be it native or implanted cells. In addition, a porous surface allows for the diffusion of nutrients and the establishment of a vascular network into the biomaterial construct (Beahm *et al.*, 2003).

There are two general strategies for introducing the cell-polymer constructs back into the body in order to engineer tissues. The constructs can be implanted using an open surgical procedure (implantable material) (Fig. 36.1) or introduced in a minimally invasive manner utilizing syringes or endoscopic delivery (injectable materials) (Fig. 36.2). Implantable forms of materials are typically foams, sponges, films, and other solid devices. The typical injectable forms of materials include hydrogels and microbeads. Most synthetic polymers, such as aliphatic polyesters, polyanhydrides, poly(amino acid)s, and poly(ortho ester)s, are suitable for the fabrication of implantable devices. On the other hand, natural polymers, including alginate, chitosan, hyaluronic acid, and collagen, are good examples of injectable materials. Hydrogels are highly attractive due to the potential to implant into the body in a minimally invasive manner via injection (Lee and Mooney, 2001). Their properties can be engineered for biocompatibility, selective permeability, mechanical and chemical stability, and other requirements as specified by the application (Jen *et al.*, 1996). Certain polymers, such as the polyanhydrides and collagen, can be used in both types of applications (Anseth *et al.*, 1999; Doillon *et al.*, 1994).

#### Implantable Materials

A variety of polymers can be utilized to form solid or macroporous scaffolds for tissue-engineering applications (Fig. 36.3). Aliphatic polyesters of poly(glycolic acid) (PGA) and poly(lactic acid) (PLA) are well-characterized synthetic biodegradable polymers that have been widely applied to the biomedical field generally and to the tissue-engineering arena specifically (Wong and Mooney, 1997). PGA has a high crystallinity, a high melting temperature, and low solubility in organic solvents. PLA has a much more hydrophobic character than PGA due to the introduction of the methyl group. PLA has low water uptake, and its ester bond is less labile to hydrolysis, owing to steric hindrance of the methyl group. Therefore, PLA degrades more slowly and has a higher solubility in organic solvents than PGA. Copolymers of PLA and PGA can be readily synthesized, and their physical properties are regulated by the ratio of glycolic acid to lactic acid. This enables these copolymers to be used in various applications as biodegradable matrices in tissue engineering (Mooney *et al.*, 1995).

These aliphatic polyesters can readily be processed into various physical forms appropriate for tissue-engineering applications. A number of techniques have been proposed to generate a highly porous structure of scaffolds, including solvent casting/particulate leaching (Mikos *et al.*, 1994),

phase separation (Lo *et al.*, 1995), emulsion freeze-drying (Whang *et al.*, 1995), fiber extrusion and fabric formation (Freed *et al.*, 1994), and gas foaming (Harris *et al.*, 1998; Mooney *et al.*, 1996a). Nonwoven fabrics of PGA were stabilized by spraying with PLA or PLGA solution to resist significant compressional forces and used successfully to culture smooth muscle cells (Kim and Mooney, 1998b), even with a tubular structure (Mooney *et al.*, 1996c). The gas foaming and particulate leaching provided efficient techniques for generating open pore structures, and since this gas-foaming process requires no organic solvents or high temperature, biologically active molecules can be incorporated into these matrices without denaturation (Shea *et al.*, 1999; Sheridan *et al.*, 2000). Implantation of porous polymer scaffolds leads to host tissue ingrowth and formation of granulation tissue throughout the scaffold (Fig. 36.4). Investigations have been conducted using Matrigel (reconstituted basement membrane of mouse tumor) and fibroblast growth factor 2 (FGF-2) to induce *in situ* adipogenesis. Matrigel consists largely of type IV collagen, laminin, and perclan. Preliminary results have demonstrated the migration of native preadipocytes as well as endothelial cells into the gel matrix when injected into the subcutaneous tissue (Beahm *et al.*, 2003; Patrick, 2004; Walton *et al.*, 2004). Another approach, using the theme of *in situ* adipogenesis, involves the direct association of an implant with a preexisting blood supply. Experiments with nude mice have been performed in which silicone molds packed with poly(glycolic acid) (PGA) fibers were sewn to the inferior epigastric blood vessels. These silicone molds were injected with a combination of Matrigel and FGF-2. *In situ* adipogenesis was demonstrated over a 4- to 20-week time course. Additional studies have been conducted with microspheres composed of poly(L-lactico-glycolic acid)/polyethylene glycol (PLGA/PEG) that were implanted into the abdominal fascia of rats. These microspheres were injected with insulin, insulinlike growth factor, and FGF-2. Adipose tissue was evidenced in the microspheres four weeks following implantation (Patrick, 2004; Yuksel *et al.*, 2000).

Patel *et al.* (2005) conducted studies with four variations of polyethylene glycol (PEG) scaffolds. These groups consisted of unmodified PEG, PEG modified with a degradation peptide (LGPA) that allows enzymatic hydrolysis of the material, PEG modified with a laminin adhesion peptide (YIGSR), and PEG with both modifications. The individual groups of scaffolds were seeded with rat preadipocytes and evaluated for cell viability and proliferation. Out of the four groups, the PEG scaffolds that were modified with YIGSR and LGPA allowed for cellular adherence and proliferation. The seeded preadipocytes survived longer and proliferated to a greater extent than the other samples. The biodegradability of the scaffold was thought to allow the cells more physical space to proliferate, and thus they were not limited by contact inhibition (Patel *et al.*, 2005).

Nondegradable polymers have also been examined for tissue reconstruction. For example, *in vitro* studies have been conducted with fibronectin-coated polytetrafluoroethylene scaffolds (PTFE). Human preadipocytes have been shown successfully to attach, proliferate, and differentiate into adipocytes on the PTFE scaffolds (Kral and Crandall, 1999).

A number of other synthetic polymers could also be utilized to fabricate scaffolds for breast-tissue reconstruction. These include polycaprolactone, polyanhydrides, poly(amino acid)s, and poly(ortho ester)s. Polycaprolactone (PCL) is also one of the aliphatic polyesters. PCL is a semicrystalline polymer with high solubility in organic solvents and low melting temperature. Since the degradation rate of PCL is much slower than that of PGA or PLA, it has been previously used as a long-term drug delivery carrier (Pitt, 1990). The biocompatibility of PCL has been investigated in a rat model (Yamada *et al.*, 1997) and a rabbit model (Lowry *et al.*, 1997). Polyanhydrides are usually copolymers of aromatic diacids and aliphatic diacids. They usually degrade by surface erosion, and their degradation rate can be controlled, depending on the choice of diacids (Domb *et al.*, 1989). The degradation rate of polyanhydrides is much faster than those of poly(ortho ester)s in the absence of any

**FIG. 36.4.** Formation of new three-dimensional tissue following implantation of a highly porous biodegradable polymer matrix. Rat adipocytes were seeded for 24 h onto a 13-mm-diameter, 3-mm-thick PLA matrix and then implanted into the subcutaneous space of a female Lewis rat. The implants were harvested four weeks postimplantation, fixed in formalin, and embedded, and 4- $\mu$ m sections were stained with hematoxylin and eosin. A 25 $\times$  magnification of the graft is shown. A well-defined tissue is present throughout the implant site, with the establishment of a vascular bed, and the matrix size and shape predetermine the size and shape of the engineered tissue mass. Unpublished data from W. D. Holder and C. R. Halberstadt.

additives. Therefore, polyanhydrides have been widely used as biodegradable implants for local drug delivery of cefazolin (Park *et al.*, 1998), bupivacaine (Park *et al.*, 1998), methotrexate (Dang *et al.*, 1994), and taxol (Fung *et al.*, 1998; Park *et al.*, 1998). Poly[bis(*p*-carboxyphenoxy)propane-sebacic acid] was approved by the FDA for clinical trials (Engelberg and Kohn, 1991). It is biocompatible and nontoxic, even in the rat brain, when compared to standard neurosurgical implants (Tamargo *et al.*, 1989). Poly(amino acid)s have been studied due to their similarity to proteins, and they have been widely investigated for biomedical applications such as sutures and artificial skin (Anderson *et al.*, 1985). Poly(amino acid)s are usually polymerized by ring-opening of *N*-carboxyanhydrides, and versatile copolymers can be prepared from various combinations of amino acids. However, due to their low solubility and limited processability, pseudo-poly(amino acid)s have also been developed, by Kohn and Langer (1987). It was also reported that poly(amino acid)s containing L-arginine, L-lysine, or L-ornithine caused endothelium-dependent relaxation of bovine intrapulmonary artery and vein and stimulated the formation and/or release of an endothelium-derived relaxing factor identified as nitric oxide (Ignarro *et al.*, 1989). Poly(ortho ester)s are biodegradable polymers, which degrade by gradual surface erosion and have been known as useful materials for controlled drug delivery. Poly(ortho ester) membranes containing indomethacin (Solheim *et al.*, 1992), gentamycin (Pinholt *et al.*, 1992), or insulinlike growth factor (Busch *et al.*, 1996) have been prepared and implanted into rats without any noticeable inflammation after degradation.

Hyaluronic acid (HA) is a natural component of the extracellular matrix of many tissues. HA comprises repeated sequences of glucuronic acid and acetylglucosamine to form a polymer. This native form is susceptible to enzymatic degradation via hyaluronidase, making the molecule unstable for biomaterial purposes. Simple modifications have been made, such as cross-linking the chains to form insoluble hydrogels (Baier Leach *et al.*, 2003). In its natural form HA plays a role in enriching wound healing by promoting early inflammation and stimulating angiogenesis (Chen and Abatangelo, 1999). Hyaluronan benzyl ester (HYAFF® 11) scaffolds are derived from hyaluronic acid that is esterified with benzyl groups at the glucuronic acid monomer, and one group has experimented with these sponges by seeding them with human preadipocytes and surgically implanting them into subcutaneous tissue of athymic nude mice. They demonstrated good cellular penetration as well as development of new vascular networks within the sponges. However, adipose-tissue development remained sparse (Hemmrich *et al.*, 2005). This same group also compared collagen scaffolds to HYAFF® 11 scaffolds *in vivo* and found better results in terms of implant weight, adipose-tissue formation, and distribution of cells using the HYAFF® 11 scaffolds (von Heimburg *et al.*, 2001b).

Collagen is the best-known tissue-derived natural polymer. It is the main component of all mammalian tissues, including skin, bone, cartilage, tendon, and ligament. Collagen has been used as a tissue culture scaffold or artificial skin due to the easy attachment of many different cell types. However, collagen offers a limited range of physical properties, and it can be expensive (Pulapura and Kohn, 1992). Chemical modification and incorporation of fibronectin, chondroitin sulfate, or low levels of hyaluronic acid into the collagen matrix can affect cell adhesion (Srivastava *et al.*, 1990). Freeze-dried collagen scaffolds were compared to sponges and nonwoven mesh composed of hyaluronic acid. *In vivo* experiments were carried out in a murine animal model for eight months. The hyaluronic-based products were found to be superior to the freeze-dried collagen scaffold. Specifically, hyaluronic sponges displayed a greater number of adipocytes than the nonwoven mesh. This was attributed mainly to the porous nature of the sponge, which allowed for greater surface area for adipocyte cell distribution and growth (von Heimburg *et al.*, 2001a, 2001b).

### Injectable Materials

A number of hydrogels, mainly naturally derived, can be utilized as injectable materials. Interest in hydrogels as biomaterials has increased. These polymers are elastic in nature and generally contain over 90% water per volumetric weight. Hydrogel biomaterials possess many suitable features for tissue-engineering applications. First, they can be delivered via injection. Second, if necessary, some hydrogels can easily be modified with the addition of bioactive groups to enhance cellular interactions. These modifications include the addition of proteolytically degradable peptides to enhance the biodegradability. In addition, the adhesion peptides tyrosine, isoleucine, glycine, serine, and arginine (YIGSR) have been coupled to PEG to enhance cellular attachment (Patel and Patrick, 2004).

Alginate is a natural hydrogel that has found its widest use to date as an injectable scaffold material for tissue engineering (Atala *et al.*, 1994) due to its simple gelation properties when ionically cross-linked with divalent cations such as  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Ba}^{2+}$ , and  $\text{Sr}^{2+}$ . Because of its favorable properties, including biocompatibility, nonimmunogenicity, hydrophilicity, and relatively low cost, there have been many attempts to utilize this material as a wound dressing, dental impression, immobilization matrix, and scaffolds for cultured and transplanted cells (Gombotz and Wee, 1998; Klock *et al.*, 1997; Shapiro and Cohen, 1997). Alginate can be used in an injectable form either by being preformed into small beads or by injection before or during the solidifying process. Due to the ease of implantation in a minimally invasive manner, alginate beads have been prepared and used for the transplantation of chondrocytes (Gregory *et al.*, 1999; Lemare *et al.*, 1998) or hepatocytes (Joly *et al.*, 1997).

Typical commercially available alginates are not ideal materials for tissue engineering because they do not mediate

cell adhesion, and they lose their divalent ions into the surrounding tissue and then dissolve in a poorly controlled manner. In addition, the molecular weight of many alginates is typically above the renal clearance threshold of the kidney (Al-Shamkhani and Duncan, 1995). Alginate is also known to discourage protein adsorption due to its hydrophilic character, and this may decrease the survival of many cell types in alginate hydrogels (Smetana, 1993). Bouhadir *et al.* (1999) reported the development of hydrolytically degradable, covalently cross-linked hydrogels derived from alginate. To avoid the degradation problem of alginate, polyguluronate blocks with molecular weight of 6000 Da were isolated from alginate, oxidized, and covalently cross-linked with adipic dihydrazide. The gelling of these polymers could be readily controlled, and their mechanical properties depended on the cross-linking density. It has also been demonstrated that alginate gel degradation can readily be regulated by controlling the molecular weight distribution of the polymer chains in the gels and their susceptibility to hydrolytic scission by partial oxidation (Boonthekul *et al.*, 2005).

Cellular attachment to unmodified alginate is very poor. This limitation has been overcome with molecular modification. An RGD- (arginine-glycine-aspartic acid) containing cell adhesion ligand was covalently coupled to enhance the cellular interaction with alginate hydrogels (Rowley *et al.*, 1999). These modified alginate hydrogels provided for adhesion, proliferation, and expression of differentiated phenotype of mouse skeletal myoblasts. Our group developed a method for processing the alginate-coupled RGD hydrogel into a porous bead structure that supported cell attachment and ingrowth (Fig. 36.5a) (Halberstadt *et al.*, 2002; Loeb sack *et al.*, 2001). These beads were developed to be small enough to be injected, making this material a potential candidate for cellular delivery (Halberstadt *et al.*, 2002). In addition, because of the cell adhesion peptides, these beads supported preadipocyte adhesion for transplantation (Fig. 36.5b) (Halberstadt *et al.*, 2002).

Other naturally occurring polymers can also be utilized as injectable materials for breast-tissue reconstruction. These include chitosan, hyaluronic acid, and collagen. Chitosan is the second-most-plentiful biomass, and coupling a variety of molecules to the reactive amino groups in the backbone (Lee *et al.*, 1995; Muzzarelli, 1983) has formed various derivatives of chitosan. Chitosan has been known to be biocompatible and biodegradable and has a low toxicity (Chandy and Sharma, 1990; Tomihata and Ikada, 1997). This enables chitosan to be useful for versatile biomedical applications such as plastic surgery (Biagini *et al.*, 1991) and wound healing (Muzzarelli *et al.*, 1993). Chitosan matrices were fabricated and proposed as cell substrates for bovine chromaffin cells and porcine hepatocytes due to its structural similarity to glycosaminoglycans (Elcin *et al.*, 1999; Eser Elcin *et al.*, 1998). Hyaluronic acid and its derivatives have been used as a drug delivery system (Larsen and Balazs,

1991). Hydrogels of hyaluronic acid have also been prepared by covalent cross-linking with various kinds of hydrazides (Vercruysse *et al.*, 1997). Human fibroblasts and keratinocytes were cultured on hyaluronic acid-derived biomaterials (Zacchi *et al.*, 1998), and cross-linked non-animal hyaluronic acid gel was used as facial intradermal implants (Duranti *et al.*, 1998).

The longest successful adipocyte construct utilized fibrin glue as a carrier for preadipocytes. The construct was implanted into a rat animal model, and adipose tissue was observed for one year after implantation (Wechselberger *et al.*, 2002).

## IV. ANIMAL MODELS

A primary problem with the development of tissue-engineered human-breast reconstruction or augmentation is that no specific animal models mimic the native human breast tissue. Human beings are the only animals to have well-developed breasts. Other primates may have small breast mounds, particularly when lactating, but these are inadequate for developing large tissue constructs for partial or complete mastectomy equivalent to what occurs in patients. Cattle and goats have udders that have no structural or functional similarity to humans. Rats and mice have multiple teats along mammary lines extending from the neck to the inguinal region, with small mammary glands beneath each teat. Pigs, dogs, and sheep similarly have subcutaneous mammary glands that are inconspicuous unless the animal is lactating. Despite the lack of an ideal model, major development of concepts can be achieved and important research questions answered using several animal models.

There has been excellent success using inbred female Lewis rats as a small-animal model for the development of transplantable tissues on absorbable polymers such as PGA, PLA, and PGLA and hydrogels such as alginate (Holder *et al.*, 1998). This model allows for transplantation of cells between individuals without concern for immunologic rejection, which parallels the likely autologous nature of cell transplantation for breast engineering. In addition, the Lewis rat is larger than many other strains and allows for the testing of larger (1–2 cm) or multiple constructs in the same animal. In order to prevent migration of implanted materials and to control the local formation of the engineered tissue, a “purse-string” technique has been developed to secure implants at specific sites (Loeb sack *et al.*, 2001; Roland *et al.*, 1998). Briefly, a single nonabsorbable suture is passed in and out of the skin to form a circle. The skin is lifted with forceps, forming a pocket, and the implant is placed into the subcutaneous tissue in the center of the circle through a small incision that is then sutured together. The purse-string suture is then tightened to hold the implant in place. The suture may be removed two weeks later and the implant remains in place.

Another animal model used for the transplantation of human-derived cells is either the Nude (nu/nu) or SCID

**FIG. 36.5.** (a) Cartoon of the generation of porous alginate beads. Briefly, a 3% alginate solution was mixed with 1.5% BSA and 2 M sodium bicarbonate. The solution was mixed rapidly and then drawn up into a syringe. The syringe was connected to a syringe pump, and individual drops were formed and added to a 0.5-M  $\text{CaCl}_2$  solution made in glacial acetic acid. Upon formation of the beads, they were placed into a vacuum cylinder, and the vacuum was placed in order to remove the carbon dioxide gas and form the porous beads. The insert is a laser confocal microscopic image of the porous structure of a bead (taken with permission from Loeb sack *et al.*, 2001). (b) Confocal image of sheep preadipocytes isolated from the omentum seeded onto porous alginate-RGD fragments. The cells were stained with a live/dead fluorescent probe (calcein AM/ethidium homodimer-1 — molecular probes) (5× magnification) (taken with permission from Halberstadt *et al.*, 2002).

mouse. These animals have compromised immune systems to the extent that they will often accept xenogeneic transplanted tissues, and these mice have been particularly useful for transplantation and immunologic studies of human tumors, bone marrow, skin, and other tissues (Bach-Mortensen *et al.*, 1976; Lopez Valle *et al.*, 1996; Ullmann *et al.*, 1998). They are potential models for evaluating various polymer constructs with and without human cells *in vivo* without the adverse effects of major immunologic reaction.

Further, basic questions about human cells and polymers *in vivo* may be answered without going to human trials prematurely. Development of these models may not be straightforward, since there are subtle differences between strains regarding the acceptance of various tissues and the growth of the implanted tissues in different sites (e.g., a tissue may grow in one mouse strain but not another or grow in a subcutaneous site but not in an internal location). Nude mice lack a T-lymphocyte response, while SCID mice lack both a

T- and a B-lymphocyte response. However, both types have natural killer cells that may interact with some transplanted materials. These mouse colonies must be monitored closely for changes in the immune status of the mice, which at times occur spontaneously. In addition, the transplanted human cells must be screened routinely for HIV, hepatitis, and mycoplasma before transplanting into immunosuppressed mice to ensure the safety of the animals and workers and the validity of the experiments.

In evaluating larger animals as models for breast-tissue engineering, animals with skin and subcutaneous tissues that are similar to humans are required in order to evaluate larger constructs in the subcutaneous position. For this reason, the same animal must be used as a tissue donor and a recipient. Dogs generally have little fat and very loose skin and present many of the problems of the rat in terms of migration of implanted materials. Porcine skin and subcutaneous tissues are very similar to humans, but most pigs continue to gain weight rapidly throughout their lives, which makes monitoring implants very difficult. Sheep have very little subcutaneous fat and, depending on the location, have a well-defined subcutaneous space for cellular engraftment. Hence, if new adipose tissue is formed, the probability is high that this would be developed from the implanted cells. One of the few locations in the sheep where there are significant fat deposits is the omentum. Halberstadt *et al.* (2002) demonstrated that preadipocytes isolated from the omentum could be expanded in culture and then seeded onto porous alginate-RGD fragments. The sheep preadipocytes attached, proliferated, and spread onto the biomaterial surface (Fig. 36.5b). This material was subsequently

injected into the nape of the neck of some of the sheep to determine if new adipose tissue would form. Although the cells were autologous and not labeled with a tracking marker, there appeared to be *de novo* adipose tissue formation in the cell implant sites as compared to the biomaterial-only control sites (Fig. 36.6a and b).

Further research and development will be required to establish a technology for biopsies and cellular construct implantation that is efficient, technically straightforward, and minimally invasive in any of these large-animal models.

## V. STRATEGIES TO ENHANCE THE VASCULARIZATION OF ENGINEERED TISSUE

A critical challenge to engineer breast tissue, or any tissue of significant thickness, is to develop a vascular network that can support the metabolic needs of the engineered tissue and integrate it with the rest of the body. The need for a vascular network has been strikingly demonstrated in studies of hepatocyte transplantation, in which over 90% of the cells transplanted, even on relatively thin (3-mm-thick) scaffolds, died within days following implantation (Mooney *et al.*, 1997). This finding of significant cell death prior to tissue vascularization is not unique to hepatocytes; it has also been noted in smooth muscle cell transplantation (Cohn *et al.*, 1997) and is likely a general finding in all efforts to engineer vascularized tissues (Colton, 1995). Adipose tissue is highly vascularized, possessing a resting blood flow two to three times higher than that of skeletal

**FIG. 36.6.** Autologous sheep preadipocytes harvested from the omentum were seeded onto alginate-RGD fragments, grown for three days in culture, and 2-mL fractions were injected using an 18-gauge needle into the nape of the neck. **(a)** Histological section (40 $\times$  magnification) of a three-month implant. Note the pocket of adipose tissue closely associated with the alginate matrix. **(b)** Higher magnification (200 $\times$ ) of Fig. 36.6a demonstrating a minimal inflammatory response to the alginate material and the development of adipose tissue. No adipose-tissue formation was observed in the acellular biomaterial-only controls (taken with permission from Halberstadt *et al.*, 2002).

muscle. The presence of vascularized networks in natural metabolic organs results in a short diffusion distance between the nutrient source and the cells (R. C. Thomson *et al.*, 1995), and these vascular networks must be created in engineered tissues as well. Nutrient diffusion *in vivo* is constrained to a distance of approximately 150  $\mu\text{m}$ . Most metabolically active cells that are located farther than this distance from a nearby capillary are subject to hypoxia. It can be seen that the success of any large engineered tissue hinges on its blood supply. The important interrelationship between preadipocytes and endothelial cells was demonstrated in hypoxic culture experiments. Frye *et al.* (2005) exposed cell cultures of pure preadipocytes and mixed cultures of preadipocytes along with microvascular endothelial cells to hypoxic conditions (5–2%  $\text{O}_2$ ) in specially designed chambers. Preadipocytes co-cultured with microvascular endothelial cells showed better viability than cultures consisting of preadipocytes alone. These results suggest the presence of an underlying humoral interaction between the two cell types that is stimulated by hypoxia (Frye *et al.*, 2005).

There are three general approaches taken to date to promote angiogenesis in engineered tissues. The first relies on the vascularization that accompanies the inflammatory response to any implanted foreign material. Optimization of the porosity and pore size of tissue-engineering scaffolds

can increase the rate of granulation-tissue formation in engineered tissues (Mikos *et al.*, 1993; Mooney *et al.*, 1994). However, the blood vessel ingrowth occurs slowly with this approach and will likely not be sufficient to engineer large tissue volumes. The second two approaches attempt to actively modulate the vascularization process by either delivering angiogenic molecules or blood-vessel-forming cells (e.g., endothelial cells) to the site at which the tissue is being engineered.

One attractive approach to engineering tissues in these models is to deliver cellular constructs that are approximately 500  $\mu\text{m}$  or less in thickness. This may optimize diffusional transport of nutrients to the cells while each small cell-polymer unit becomes vascularized. We have taken this approach by designing porous alginate-RGD beads (500  $\mu\text{m}$  to 3 mm in diameter) for cell transplantation (Burg *et al.*, 2000; Eiselt *et al.*, 2000; Halberstadt *et al.*, 2000; Loeb sack *et al.*, 2001). Because the beads are macroporous, the vascular endothelial cells can migrate into the beads and establish a three-dimensional vascular bed in a short time (Fig. 36.7a and b). This approach potentially can be combined with angiogenic factors and cells to enhance the timing of endothelialization to promote the survival of the transplanted cells.

Site-specific delivery of angiogenic molecules may provide an efficient means of stimulating localized vessel

**FIG. 36.7.** Cartoon drawing of an approach to create three-dimensional tissue structures. (a) Small macroporous beads seeded with cells are injected into a tissue. (b) The foreign material, coupled with an inflammatory response, initiates a vascular ingrowth into the porous beads. The use of angiogenic factors and/or endothelial cells may further enhance the complete revascularization of this injectable construct over the course of a short period of time.

formation. Controlled and sustained release of angiogenic molecules from the tissue engineering scaffolds may allow optimization of this process (Eiselt *et al.*, 1998; Lee *et al.*, 2000; Peters *et al.*, 1999a; Sheridan *et al.*, 2000) and can significantly enhance perfusion of ischemic tissues (Sun *et al.*, 2005). Various growth factors, including vascular endothelial growth factor (VEGF), basic fibroblast growth factor (FGF-2), and epidermal growth factor (EGF), could be incorporated into a polymeric matrix together and released at a controlled and sustained rate in combinations or sequences (Richardson *et al.*, 2001) for an extended period of time. Alternatively, delivery of plasmid DNA encoding the angiogenic proteins may be another approach to generate the vascular networks in engineered tissues (Shea *et al.*, 1999). PLGA scaffolds containing a plasmid encoding for PDGF, a potent angiogenesis promoter, greatly increased the number of blood vessels and granulation tissue that formed as compared to scaffolds that did not deliver the plasmid DNA (Shea *et al.*, 1999).

Another potential approach to enhance angiogenesis in engineered tissues is to cotransplant endothelial cells or progenitors along with the primary cell type of interest. This approach is suggested by the observation that endothelial cells will spontaneously form capillarylike structures *in vitro* if cultured in an appropriate environment (Ingber and Folkman, 1989; Pepper *et al.*, 1992). Endothelial cells seeded into a tissue-engineering scaffold may be able to form capillaries or capillarylike structures, which then can merge with capillaries growing into the scaffold from the host tissue. This possibility is supported by our previous finding that transplantation of syngeneic endothelial cells on polymer scaffolds led to a statistically significant enhancement in the density of blood vessels in the scaffolds following two weeks implantation into rats (Holder *et al.*, 1997). In addition, the new capillaries that form in these scaffolds comprise both the transplanted endothelial cells and ingrowing cells from the host (Nor *et al.*, 1999), and these transplanted endothelial cells enhance the survival (Smith *et al.*, 2004) and tissue formation by transplanted cells (Kaigler *et al.*, 2005). The utility of embryonic stem cell-derived endothelial cells in enhancing skeletal muscle engineering has also been demonstrated (Levenberg *et al.*, 2005).

Recently, Khademhosseini *et al.* (2006) proposed a method of using microstamping and nanofluid chambers to create a three-dimensional vascular bed for liver-tissue engineering. The long-term goal for this group is to develop a three-dimensional vascular bed *ex vivo* that could be anastomosed to the host vasculature to support cellular engraftment. Depending on the materials used, this approach could also be developed for breast-tissue engineering.

Direct application of a vascular pedicle to the construct is another promising approach. The idea of using vascular pedicles is not a novel concept. Pre-fabricated flaps have been created with vascular pedicles since the 1960s. It stands to reason that preformed vascular pedicles will enhance the growth of tissue-engineered constructs. Vascular pedicles can be supplied in many different configurations. In general, conduits composed of an intact artery and vein together fare better than those composed of a single vein alone (Erol and Spira, 1990; Walton and Brown, 1993).

## VI. SPECIAL CONSIDERATIONS

Nipple reconstruction is an additional problem that is created after mastectomy. Traditional approaches have consisted of free composite grafts, local-tissue transfer, and prosthetic devices. Free composite grafts were used early on and were created from autologous tissues, such as the labia, inner thigh, cartilage (auricular or costal), the contralateral nipple, and the toe. Complications at the graft site have since made this technique less desirable. Local-tissue flaps are the most popular routes for nipple reconstruction. Commonly used techniques include the bell flap, the modified star flap, and the skate flap (Bernard and Beran, 2003; Eng, 1996; Guerra *et al.*, 2003; Little, 1984). Unfortunately these techniques can be hindered by flap necrosis and poor aesthetic results, including loss of nipple projection. Holton *et al.* (2005) have proposed a solution to this problem using tissue engineering. Their experiments utilized human acellular matrix implants in athymic mice. Three groups were created, consisting of traditional bell flap alone, bell flap plus a cylinder composed of an acellular dermal matrix, and bell flap plus intraflap injections of micro-sized acellular dermal matrix. Bell flaps alone maintained 44% of initial projection, while flaps with acellular dermal matrix cylinders maintained 70%. However, the acellular dermal matrix cylinders were extruded in 30% of the samples. The flaps that were microinjected with acellular dermal matrix retained 49% of their original projection.

## VII. CONCLUDING REMARKS

Tissue engineering may provide a new therapy to reconstruct breast tissue for women undergoing lumpectomy or mastectomy. A number of cell types and polymeric materials may be useful to reconstruct breast tissue. In addition, it is clear that optimization of vascularization is critical to engineering large tissue constructs. This approach may ultimately allow one to engineer and reconstruct breast tissue with less pain and less invasive methods than those currently utilized clinically.

### I. INTRODUCTION

This chapter discusses the role that endogenous and exogenous progenitor cells may play in the maintenance of cardiac homeostasis, organ repair after injury, and the treatment of the diseased heart. The recognition that the adult heart possesses a stem cell compartment that can regenerate myocytes and coronary vessels has raised the possibilities of rebuilding infarcted myocardium, replacing old hypertrophied and poorly contracting myocytes with new, better-functioning cells, and, perhaps, reversing ventricular dilation and wall thinning. Similarly, adult bone marrow cells are able to differentiate into cells beyond their own tissue boundary and to create cardiomyocytes and coronary vessels. This process has been termed *developmental plasticity* or *transdifferentiation*. These observations have challenged the view of the heart as a postmitotic organ and have proposed a new paradigm, in which cardiac cells are continuously replaced by newly formed myocytes and vascular cells.

### II. ORGAN HOMEOSTASIS

The balance between cell death and cell division is crucial for the preservation of cell number and organ mass in prenatal and postnatal life. The size of an organ is determined by the average volume of the parenchymal cells and the total number of these cells. These parameters are controlled by the rate of cell division, migration, growth, and death. The existence of an intrinsic mechanism that enables an organ to sense its own size and regulate its growth has been postulated, but the demonstration of this regulatory process remains elusive. When the human liver is surgically reduced, the parenchyma regenerates itself until the correct organ size is achieved. Similarly, the growth of fetal thymus glands transplanted into adult mice stops when the postnatal dimension is reached. The same pattern of growth takes place when a larval wing disc is transplanted into an adult fly. These observations support the notion that a conserved, organ-autonomous apparatus for the modulation of organ volume is present across species in prenatal life (Doseff *et al.*, 2004).

How organ growth in the embryo is regulated is largely unknown. However, it is reasonable to assume that the activation of a complex network of growth-inducing factors, negative feedback loops that decrease the rate of growth, together with the induction or inhibition of apoptosis, takes place when the organ either exceeds or does not reach the “organ-size checkpoint.” Adult organ homeostasis may be modulated in a similar manner, but these processes are expected to become dysfunctional with aging and the appearance of diseases. Postnatally, decreases in the number of cells within an organ may be compensated by enhanced cell proliferation or by enlargement of the remaining parenchymal cells, which attempt to preserve organ dimension. In newts, *Drosophila*, and higher eukaryotes, the maintenance of the size of a given organ in the organism can be accomplished by a larger number of smaller cells or a smaller number of larger cells (Gomer *et al.*, 2001). These two distinct adaptations have different histological features but, most importantly, are not functionally equivalent. In this regard, the hypertrophic response of cells can become rapidly maladaptive because of the difficulty of the larger cells’ performing efficiently a variety of specialized functions.

Although cellular hypertrophy can reconstitute a correct organ volume, actual repair is achieved through cell regeneration, which results in the replacement of the cells lost following injury by new, functionally competent cells. In physiological conditions, this process is highly efficient; cell dropout by normal wear and tear is counteracted by cell regeneration, and organ homeostasis is preserved. Conversely, in the presence of damage, restitutio ad integrum does not occur, and healing is associated with the formation of a scar. Scarring is crucial for rapid handling of the damage, to seclude the lesion from healthy tissue and to prevent a cascade of uncontrolled deleterious events (Mutsaers *et al.*, 1997). However, the fibrotic area does not possess the biochemical, physical, or functional properties of the uninjured tissue. By necessity, the reparative response, which occurs in damaged organs, leads to scarring and cellular hypertrophy. Both cellular phenomena affect the overall performance of the organ (Silver and Miller, 2004).

In spite of the presence of resident stem cells, spontaneous tissue regeneration is a rare event in adult self-renewing organs (Watanabe *et al.*, 2003). It is unknown why the evolution of a lesion is different in prenatal and postnatal life. In fact, tissue repair in early mammalian embryos is rapid, efficient, and scar free (Ferguson and O’Kane, 2004), and skin wounds heal with restitutio ad integrum, whereas wounds in adult mammals result in scarring. The difference in the inflammatory response may condition the distinct evolution of the healing process in embryos and adults. In the embryo, a lower number of less differentiated inflammatory cells accumulate in the region of damage, and the growth factors present at the site of healing are highly variable with respect to those in the adult tissue. In the latter case, the secretion of cytokines may influence negatively the

regenerative ability of adult stem cells and might ultimately oppose their survival, interfering with the restoration of the damaged organ.

Interventions aiming at the recapitulation of the embryonic gene program could be fundamental for effective organ repair. Recent evidence points to the importance of morphogens for proper homeostasis. During normal development, cells have different fates, according to the distribution of morphogens, which are signaling proteins that set the positional value of a cell. They form concentration gradients across the developmental field in which the cells reside, determining their fate (Tabata and Takei, 2004). The effects of morphogens on the developing cells depend on the distance between the receiving cells and the morphogen-secreting cells. The *Drosophila* wing is considered a good model for the study of patterning; Decapentaplegic, Wingless, and Hedgehog proteins have been shown to act as morphogens in this system (Tabata and Takei, 2004).

In addition to the effect on cell fate, morphogens can function as chemoattractants or chemorepellents modulating the migration of cells. This phenomenon is apparent during neural crest development (Jones and Trainor, 2005). Morphogens regulate both induction and migration of this stem cell population that generates a variety of tissues, including Purkinje neurons, glia, heart, smooth muscle, connective tissue, melanocytes, craniofacial cartilage, and bone. Finally, the rates of cell division and cell apoptosis have to be tightly regulated to allow the survival of the correct cells in a system in which cells compete for the same trophic factors. Cell competition results in apoptosis of slower-growing cells located in proximity to faster-growing cells. C-myc up-regulation transforms cells in “supercompetitors,” which become capable of clonal expansion (Secombe *et al.*, 2004). The cluster of supercompetitor cells influences the behavior of the surrounding cells, favoring the onset of apoptotic death in the more vulnerable subset. These cells are at a disadvantage, which is created by the low level of this oncogene. Although this cross-talk has been identified in *Drosophila* (Secombe *et al.*, 2004), it might be important in mammals as well. Cell competitions may lead to mechanical stresses within an organ or tissue, which, in turn, provide a feedback loop aiming at the stabilization and uniformity of cellular growth processes.

Based on this information, it might be reasonable to postulate that the objective of regenerative medicine is the polarization of cell-fate choices, pattern formation, and tissue reconstitution. To achieve this ambitious goal, cellular, genetic, biochemical, and molecular approaches need to be implemented concurrently to identify and characterize cellular mechanisms, modify their undesired evolution, reprogram their transcriptional targets, and force the acquisition of novel identities. The possibility of operating at these new levels of cell-fate determinants may alter the evolution of a damaging event and its impact on organ integrity,

structurally and functionally. At present, our understanding of the fundamental biological principles of cell behavior is inadequate to address these issues, which are critical for the restoration of baseline physiological performance following injury.

### III. CARDIAC HOMEOSTASIS

According to the old view of cardiac biology, the heart survives and exerts its function until the death of the organism with the same number of cells as, or fewer cells than, are present at birth (Chien, 2004). Thus, the heart would respond to parenchymal losses only by increasing the size of its cells, without any form of regeneration. If this were the case, the protection of organ size in physiological situations would occur at the price of a progressive deterioration of cardiac function. In fact, normal wear and tear leads to continuous cell dropout, and this loss would be compensated by uniform enlargement of cardiomyocytes. Hypertrophied myocytes are poorly contracting cells characterized by profound alterations of intracellular calcium cycling, and this defect inevitably contributes over time to the onset of ventricular dysfunction and its progression to cardiac failure (Leri *et al.*, 2005).

The novel view of the heart as an organ with regenerative ability implies that the reconstitution of muscle mass can be achieved not only by increasing myocyte volume but also by promoting myocyte proliferation. In embryonic and early postnatal life, the increase in cardiac mass reflects the delicate balance between the addition of new myocytes and the death of unnecessary cells (Olson *et al.*, 1996). Shortly after birth, cardiac growth occurs by means of an increase in myocyte number and volume, which together participate in the development of the adult heart phenotype (Anversa and Olivetti, 2002). In adulthood, the heart is characterized by a surprisingly high and rapid turnover of its parenchymal cells that is regulated by a stem cell compartment (Anversa *et al.*, 2006).

An *in vivo* functional assay that allows the evaluation of cell turnover in self-renewing organs consists of the pulse-chase labeling protocol. By this approach, the growth and phenotypic changes occurring in cardiac stem cells (CSCs) during their transition from a poorly differentiated to a specialized compartment can be identified.

To determine the activation of CSCs in the mouse heart, 4 and 12 injections of BrdU were performed at 12-hour intervals in two groups of mice over a period of two and six days, respectively. A third group of mice was treated in an identical manner for six days, and mice were sacrificed after a chasing period of 10 weeks. Bright and dim BrdU labeled Lin<sup>+</sup>CSCs were distinguished based on fluorescence intensity. The number of bright BrdU Lin<sup>+</sup>CSCs in the atria increased 140% from two to six days but decreased 91% after 10 weeks of chasing. Of 257 bright BrdU-Lin<sup>+</sup>CSCs at six days, only 23 cells retained this characteristic at 10 weeks, constituting the slow-cycling SC pool in this portion of the

heart. A similar pattern of changes was seen in the base-midregion and apex. Dim BrdU-Lin<sup>+</sup>CSCs increased from two to six days, but, in contrast to bright BrdU-Lin<sup>+</sup>CSCs, dim BrdU-Lin<sup>+</sup>CSCs increased dramatically after chasing, 16-fold in the atria, 13-fold at the base-midregion, and 16-fold at the apex. The aggregate number of Lin<sup>+</sup>CSCs did not change over a period of 10 weeks, indicating that the growth kinetics of Lin<sup>+</sup>CSCs tends to preserve the pool of primitive cells in the young, healthy heart (Urbanek *et al.*, 2005).

The long-term label-retaining assay documented that ~10% of Lin<sup>+</sup>CSCs are slow cycling and conform to the paradigm of SCs. By employing the same approach, myocyte formation was assessed by measuring the fraction of BrdU<sup>POS</sup>-cells. After 10 weeks of chasing, BrdU-bright myocytes were cells that experienced a limited number of divisions, while more rounds of doublings had to occur in myocytes with intermediate levels of labeling. These myocyte classes were assumed to correspond to amplifying myocytes, which incorporated BrdU at the time of injection and continued to divide and differentiate. Conversely, BrdU-dim myocytes were considered the progeny of cycling CSCs, which became BrdU<sup>POS</sup> at the time of injection and gave rise to a large number of committed cells. The percentage of BrdU-bright-myocytes detected at six days decreased markedly after 10 weeks, while BrdU-dim-myocytes increased. The apex had 19% BrdU-labeled myocytes, the atria 15%, and the base-midregion 10%. In two and a half months, ~10–19% of atrial and ventricular myocytes were formed. In spite of this large increase in the number of parenchymal cells, the total number of atrial and ventricular myocytes remained constant, suggesting a high turnover of this cell population.

However, myocyte renewal was not homogeneous, and the rate of cell regeneration was higher in the atria and apex than at the base-midregion of the left ventricle. Importantly, the heterogeneity of myocyte regeneration in these anatomical sites was paralleled by a similar heterogeneity in the number of CSCs, since the higher numerical density of CSCs per unit volume of myocardium was associated with the larger formation of cardiomyocytes. These data provide information on the magnitude of cell turnover in the myocardium. These results were complemented with the measurements of myocyte progenitors-precursors, which together with CSC number were utilized to evaluate the half-life of myocytes. Contrary to expectations, myocytes located at the base-midregion have a half-life twofold longer than atrial and apical myocytes, suggesting that myocyte turnover is high and heterogeneous. By this novel analysis, we found that 50% of ventricular myocytes are lost in approximately nine months, while this phenomenon is faster at the apex and atria, requiring less than four months. The degree of turnover is inversely related to the level of hemodynamic stress in the heart. It is unknown why higher workload is associated with a longer myocyte life span. The ventricle represents the region that mostly par-

ticipates in the pump function, and the heart would fail if ventricular myocytes were to be engaged too often in mitotic division (Urbanek *et al.*, 2005). Together, these observations challenge the notion that the life span of myocytes coincides with the life span of the organ and the organism (MacLellan and Schneider, 2000) and the contention that myocyte regeneration is a slow, inconsequential process of heart homeostasis (Chien, 2004). Conversely, myocyte replication is constant and heterogeneous and involves a large number of cells.

Under physiologic conditions, the intrinsic growth reserve of the heart is sufficient to maintain cell homeostasis and adequate pump performance. However, when an increase in pressure and/or volume load is imposed on the heart, myocyte hypertrophy and proliferation, in combination with myocyte apoptosis and necrosis, constitute the elements of myocardial remodeling (Pfeffer and Braunwald, 1990). Novel methodological approaches applied to the analysis of the myocardium have defeated the paradigm, introduced more than 60 years ago, that the heart is a post-mitotic organ and that myocytes are terminally differentiated cells that participate in cardiac function throughout life. A subset of parenchymal cells expresses the molecular components mediating the entry and progression of these cells through the cell cycle and karyokinesis and cytokinesis. The recognition that myocyte replication, hypertrophy, and death occur in the pathologic heart has significantly enhanced our understanding of the dynamic nature of the myocardium and the critical role these variables have in the preservation of cardiac performance or in the onset of ventricular dysfunction (Anversa and Kajstura, 1998).

Contrary to the general belief, the restricted regenerative capacity of the myocardium does not represent the initial causal event of impaired cardiac function. The nonischemic failing heart, in its early phases of decompensation, has a number of myocytes that often exceeds the number of cells in a normal heart. Alternatively, the modest reduction in myocyte number chronically is not consistent with the severe deterioration in ventricular performance. A typical example is found in hypertensive cardiomyopathy or chronic aortic stenosis in animals and humans (Olivetti *et al.*, 1987, 1994). The initiation and evolution of cardiac failure appears to depend mostly on two other crucial factors that are strictly interrelated in the determination of pump function: the accumulation of old, poorly contracting cells and the formation of multiple foci of myocardial scarring (Wei, 1992).

The formation of new myocytes defeats the notion that cardiac cells have the same age. During aging and in pathologic states, the continuous turnover of myocytes results in a heterogeneous cell population consisting of young, adult, old, and senescent myocytes. Data in humans suggest that this subdivision corresponds to cells of different sizes, raising the possibility that the life span of a cell is associated with a progressive increase in volume of the cell. Young,

**FIG. 37.1.** Myocardial regeneration in the infarcted human heart. A cluster of highly proliferating, small, developing myocytes is visible. Myocytes are labeled by  $\alpha$ -sarcomeric actin (red) and nuclei by DAPI (blue). Most of these cells are positive for the marker of the cell cycle, Ki67 (yellow, arrowheads). The proliferating myocytes have a small cross-sectional area.

amplifying, dividing myocytes are less than  $180\ \mu\text{m}^2$  in cross-sectional area, adult nondividing cells are  $200\text{--}250\ \mu\text{m}^2$  in cross-sectional area, old nondividing  $\text{p16}^{\text{INK4a}}$ -negative cells are  $300\text{--}500\ \mu\text{m}^2$  in cross-sectional area, and senescent nondividing  $\text{p16}^{\text{INK4a}}$ -positive cells are  $600\text{--}900\ \mu\text{m}^2$  in cross-sectional area (Urbanek *et al.*, 2003). Myocyte length, however, remains relatively constant in all these cell categories, varying at most from 90 to  $120\ \mu\text{m}$ . Importantly, young myocytes do not express inhibitors of the cell cycle, such as p53 and  $\text{p16}^{\text{INK4a}}$  (Sherr and Roberts, 2004). In contrast, a large fraction of these cells, 10–15%, is cycling (Fig. 37.1), as demonstrated by BrdU, Ki67, MCM5, and Cdc6 labeling (Whitfield *et al.*, 2006). Adult myocytes are unable to reenter the cell cycle, since they are terminally differentiated. They express  $\text{p21}^{\text{Cip1}}$  but not p53 and  $\text{p16}^{\text{INK4a}}$ . Old myocytes express p53 and  $\text{p21}^{\text{Cip1}}$  in the absence of  $\text{p16}^{\text{INK4a}}$ , and senescent myocytes express p53 and  $\text{p16}^{\text{INK4a}}$  (Urbanek *et al.*, 2003).  $\text{p16}^{\text{INK4a}}$  and p53 are markers of cellular aging. Myocyte aging and the concomitant increase in myocyte volume typically result in a severe depression in cell function and in calcium metabolism.

Reduced regenerative responses dictated by deregulation of morphogens and/or limited cell proliferation has been associated with the onset of multiple cardiac diseases, and the possibility has been raised that the postnatal recapitulation of embryonic pathways promotes the regenerative response of the postnatal heart after injury. In this regard, intramyocardial gene transfer of naked DNA encoding human sonic hedgehog had a favorable impact on the recovery of the adult heart following acute and chronic

ischemia (Kusano *et al.*, 2005). This positive response was mediated by enhanced vasculogenesis, reduced fibrosis and collagen deposition, and decreased myocyte apoptosis. This and similar observations strongly indicate that gene therapy may be beneficial in various diseases by triggering the expression of multiple trophic factors and promoting tissue repair in the adult heart.

This novel view of cardiac biology has introduced the concept of the heart as an organ permissive for myocardial regeneration mediated by the activation, proliferation, and differentiation of exogenous or endogenous primitive cells. Thus, tissue damage can be replaced by the formation of new, functionally competent myocytes and coronary vessels. Cardiac repair is conditioned by several factors, including (a) the number of cells to be administered, (b) cell death and survival in the hostile milieu of the acute and chronic injured areas, (c) cell engraftment, and (d) cell growth and differentiation. An additional critical variable when exogenous cells are involved in myocardial restoration is their level of plasticity, which is dictated by their ability to acquire the myocyte and vascular smooth muscle (SMC) and endothelial cell (EC) lineages. In an identical manner, resident cardiac progenitor cells (CPCs) have to promote the formation of a proportional number of parenchymal cells and coronary vessels. Moreover, progenitor cells can contribute indirectly to cardiac regeneration by releasing a variety of peptides that exert a paracrine action on the myocardium and its resident CPCs. These mechanisms are not mutually exclusive, and primitive cells may participate both directly and indirectly in the repair process (Gnecchi *et al.*, 2005; Yoon *et al.*, 2005). In all cases, progenitor cells have to engage themselves in homing into the myocardium to perform specific functions. These biological processes depend on a successful interaction between progenitor cell classes and tissue microenvironment and condition the efficiency of repair in multiple models of myocardial regeneration.

#### IV. PROPERTIES OF EXOGENOUS AND ENDOGENOUS CELLS FOR CARDIAC REPAIR

Acutely after ischemic injury, the healing process inevitably results in scar formation, not only in the heart but also in other organs, whether their parenchymal cells are highly proliferating, slowly cycling, or terminally differentiated (Beltrami *et al.*, 1994; Silver and Miller, 2004; Leong and Freeman, 2005). The need to overcome this biological obstacle has favored the development of strategies aiming at the replacement of dead tissue with viable cells. Several interventions have been used in an attempt to promote cardiac regeneration experimentally. These protocols have employed different cell types, including fetal tissue and fetal and adult cardiomyocytes (Leor *et al.*, 1996), skeletal myoblasts (Menasche *et al.*, 2001), embryonic-derived myocytes and

**FIG. 37.2.** Culture of cardiac stem cells. c-kit positive cardiac stem cells were isolated from a human heart by enzymatic dissociation and selection with immunomagnetic beads. Cells express c-kit in the plasma membrane (green), and nuclei are stained by propidium iodide (red).

endothelial cells (Etzion *et al.*, 2001), bone marrow-derived immature myocytes (Hattan *et al.*, 2005), fibroblasts, smooth muscle cells (Li *et al.*, 1999), and bone marrow c-kit positive and negative progenitor cells (Orlic *et al.*, 2001; Kawada *et al.*, 2004; Yoon *et al.*, 2005). In spite of these efforts, however, the most appropriate form of cell therapy for actual restitutio ad integrum of the damaged myocardium has not been identified yet.

The most logical and potentially powerful cell to be employed is the cardiac progenitor cell (Fig. 37.2). It is intuitively apparent that if the adult heart possesses a pool of primitive multipotent cells (Beltrami *et al.*, 2003; Oh *et al.*, 2003; Matsuura *et al.*, 2004; Martin *et al.*, 2004; Pfister *et al.*, 2005; Messina *et al.*, 2004; Rosenblatt-Velin *et al.*, 2005; Tomita *et al.*, 2005), these cells must be tested first, before more complex and unknown cells are explored. Cardiac regeneration would be accomplished by enhancing the normal turnover of myocardial cells. CPCs may be activated locally within the myocardium, and some of the growth factor–receptor systems that regulate CSC proliferation and differentiation have been recognized (Linke *et al.*, 2005; Urbanek *et al.*, 2005). Although the importance of resident CSCs in organ homeostasis is apparent and, in the future, CSCs may become the most appropriate form of cell therapy for the diseased heart, emphasis currently has been placed on the identification of exogenous sources of highly proliferating cells that can acquire the cardiac phenotypes.

Difficulties exist in the acquisition of myocardial samples in humans and in the isolation and expansion of CPCs in quantities that can be employed therapeutically.

Conversely, bone marrow progenitor cells (BMPCs) constitute an appealing form of cell intervention; BMPCs can easily be collected from bone marrow aspirates or the peripheral blood after their mobilization from the bone marrow with cytokines. At present, it is unknown whether CPCs and BMPCs are similarly effective in reconstituting dead myocardium after infarction or whether limitations exist in CPC growth and BMPC transdifferentiation resulting in inadequate restoration of lost tissue. Also, BMPCs may constitute a necessary initial form of intervention for the infarcted heart, whereas CPCs might be employed later during the chronic evolution of the cardiac myopathy. Thus, a fundamental question to be addressed in future studies is whether BMPCs are superior, equal, or inferior to CPCs for the regeneration of cardiomyocytes and coronary vessels in ischemic heart failure.

### Hematopoietic Stem Cells

The bone marrow can be subdivided into a hematopoietic cell compartment and a stroma composed of mesenchymal stem cells (MSCs), fibroblasts, adipocytes, and vascular and nervous structures. Hematopoietic stem cells (HSCs) are the first tissue-specific compartment of stem cells that have been described (Till *et al.*, 1964a). As a consequence, the features of all stem cells in adult organs are typically studied on the basis of the characteristics of these primitive blood-forming cells. It has to be emphasized, however, that these criteria cannot be translated without caveats to solid organs and their resident stem cells. HSCs were originally identified as clonogenic cells of bone marrow origin that gave rise to multilineage hematopoietic colonies in the spleen (Till *et al.*, 1964b). In addition to the three fundamental attributes of self-renewal, clonogenicity, and multipotentiality, HSCs were defined as units of a hierarchically structured system formed by three main cellular components: primitive cells, intermediate stages, and mature cells. On this basis, all stem cell-regulated organs were recognized to adhere to a model of progressive acquisition of differentiation by primitive stem cells, which undergo maturation into progenitors, precursors, amplifying cells, and eventually terminally differentiated cells.

This succession of events was considered irreversible. However, recent work has indicated that, at least at the stem/progenitor level, hematopoiesis may be a continuum of transcriptional opportunity. The most primitive HSCs are either continually cycling at a slow rate or entering and exiting cell cycle. The cell cycle passages are accompanied by changes in functional phenotype, including reversible modifications in homing and engraftment ability, adhesion protein expression, and cytokine receptor expression (Quesenberry *et al.*, 2002). Similarly, the differentiation potential of HSCs varies in the different phases of the cell cycle. Thus, the bone marrow corresponds to a system in which cells continually shift from the engraftable primitive state to the multifactor responsive progenitor cells. These

phenotypical changes occur in both directions and do not coincide with differentiation events. They are dictated by chromatin-remodeling and epigenetic mechanisms (Quesenberry *et al.*, 2004). These observations indicate that bone marrow stem cells and most likely all adult stem cells should be not be studied as discrete entities but defined as functional units (Blau *et al.*, 2001).

Cell epitopes are commonly employed to isolate HSCs from the whole bone marrow. Different antigens characterize HSCs in different species. Mouse HSCs correspond to a subpopulation of bone marrow cells (BMCs) that are lineage negative and c-kit<sup>+</sup>Sca-1<sup>+</sup>Thy-1<sup>low</sup> (Uchida and Weissman, 1992). This population is multipotent and repopulates the bone marrow of irradiated mice. However, the c-kit<sup>+</sup>Sca-1<sup>+</sup>Thy-1<sup>low</sup> cells are functionally heterogeneous. Based on the identification of additional surface markers and clonal analysis, the Mac-1<sup>+</sup>CD4<sup>+</sup> cells within this category are enriched for long-term reconstituting cells (Morrison and Weissman, 1994). Conversely, the Mac-1<sup>low</sup>CD4<sup>+</sup> negative pool contains short-term repopulating cells. Finally, the Mac-1<sup>low</sup>CD4<sup>low</sup> cells correspond to transient multipotent progenitors together with B-lymphocyte progenitors (Morrison *et al.*, 1995). Even by using these complicated combinations of markers, only 20% of the intravenously injected cells give long-term multilineage reconstitution in most studies. The use of the Hoechst efflux dye protocol has led to the isolation of a more functionally homogeneous cell population (Goodell *et al.*, 1996). This approach, however, cannot be used for the recognition of stem and progenitor cells in tissue sections.

The expression of different members of the SLAM family of receptors has recently been correlated with the primitiveness of bone marrow cells. HSC activity was found to be present in the CD150<sup>+</sup>/CD244<sup>+</sup>/CD48<sup>+</sup> compartment but rarely in the CD150<sup>+</sup>/CD244<sup>+</sup>/CD48<sup>+</sup> fraction (Kiel *et al.*, 2005). The CD150<sup>+</sup>/CD244<sup>+</sup>/CD48<sup>+</sup> fraction of bone marrow cells represents only 0.008% of bone marrow cells and one in approximately five injected cells engrafts and yields long-term multilineage reconstitution. These results are similar to those obtained with lineage-negative c-kit<sup>+</sup>Sca-1<sup>+</sup>Thy-1<sup>low</sup> cells. Cells with SLAM receptors can easily be recognized *in vivo*, and their identification does not require the documentation of the lack of markers of commitment (Yilmaz *et al.*, 2006). The vast majority of CD150<sup>+</sup>/CD244<sup>+</sup>/CD48<sup>+</sup> cells have been found to be associated with both sinusoids and endosteum in close contact with endothelial cells and osteoblasts, respectively (Kiel *et al.*, 2005). This preferential localization within the osteoblastic and vascular niches represents an additional proof of the stemness of this cell subset.

The CD34 antigen has been used to sort human HSCs (Negrin *et al.*, 2000), which, however, are also present in the CD34 negative fraction. AC133 is another marker of human HSCs (Bhatia, 2001), but so far there is no specific epitope for the true stem cell in humans. A mixed population of bone marrow cells, rather than a highly purified stem cell

pool, has commonly been used for the restoration of injured organs (Britten *et al.*, 2003; Poulsom *et al.*, 2003).

### Mesenchymal Stem Cells

Stromal cells or MSCs are easily defined *in vitro*, where they constitute the nonhematopoietic and adherent cell component in long-term cultures. *In vivo*, they contribute to the formation of the hematopoietic microenvironment. Over 40 years ago, Friedenstein (1961) described the isolation of stromal cells from the bone marrow. Once in culture dishes, these cells, later called MSCs, assume a spindle shape and proliferate to form colonies. These cells rapidly adhere to plastic and are able to differentiate under defined *in vitro* conditions into three lineages: osteoblasts, chondroblasts, and adipocytes. Recently, the differentiation or transdifferentiation potential of MSCs appears to be much broader. MSCs can give rise to multiple cell lineages of the three germ layers: mesodermal (skeletal myoblasts, cardiac myocytes, endothelial cells), endodermal (lung cells, hepatocytes, gut cells), and ectodermal (neural cells).

In a manner similar to other adult stem cell types, MSCs are clonogenic, self-renewing, and multipotent. However, not all reports agree that MSCs possess the self-renewal property (Dennis and Charbord, 2002). If self-renewal were a feature of MSCs, this property would not be crucial for MSC function. This is because of the high degree of plasticity of MSCs, which would confer on these cells phenotypic flexibility and the ability to switch from one cell type to another, at early as well as at late stages of differentiation (Bianchi *et al.*, 2001). In view of the great level of cellular heterogeneity and the absence of clear phenotype markers, it is, however, difficult to establish whether MSCs actually transdifferentiate or constitute progenitor cells with a broad differentiation potential into all the cell lineages of mesenchymal origin. In cases in which MSCs give rise to tissues of ectodermal or endodermal origin, like the brain and the pancreas, respectively, the occurrence of transdifferentiation can be claimed.

MSCs correspond to stromal cells, constituting also structural components of the bone marrow that support hematopoiesis *in vivo* and *in vitro* by providing extracellular matrix components, cytokines, and growth factors. One of the major difficulties encountered in the utilization of MSCs in the regeneration of the injured heart is that the non-hematopoietic compartment of bone marrow consists of multiple heterogeneous cell populations. In the last several years, efforts have been made to develop protocols for the separation and enrichment of the different cellular subsets. After density-gradient fractionation, the cells in the upper low-density portion of bone marrow aspirates are plated and the nonadherent hematopoietic cells are removed by medium replacement. Only 0.001–0.01% of the initial unfractionated bone marrow cell population consists of MSCs (Pittenger and Martin, 2004). Methods based on immunological properties have been used to enrich bone

marrow for the MSC subset. MSCs are negative for hematopoietic surface markers and positive for a wide array of surface proteins. The first antigens to be associated with MSCs were those reactive with the monoclonal antibodies SH2 and SH3, which recognize CD105 and CD73, respectively (Haynesworth *et al.*, 1992). Although CD105 is a relevant epitope of MSCs and angiogenesis, CD29, CD44, CD166, CD54, CD55, CD13, and CD90 have been proposed to be important determinants of the mesenchymal phenotype (Pittenger and Martin, 2004), while STRO-1 may identify an immature state (Gronthos *et al.*, 1994). Prockop and others (Smith *et al.*, 2004) support the notion that MSCs cannot be distinguished solely by antigen expression but necessitate functional assays demonstrating their multipotent growth and differentiation behavior. Thus, a definitive consensus on the properties of MSCs has not been reached yet, and discrepancies exist in the characteristics of the distinct MSC populations employed. The differences may be explained by dissimilarities in culture methods, donor age, and differentiation stage of the cells, but this phenomenon makes comparisons among studies extremely complex.

In adulthood, the bone marrow and the systemic circulation constitute the main sources of MSCs, although they have also been detected in tissues distant from the bone marrow. The oval cells of the liver, prostatic stem cells, metanephric mesenchymal cells, precursors of the Leydig cells in the testis, primitive osteoprogenitors, preadipocytes, and satellite cells of the skeletal muscle have been classified as MSCs. Because not all studies agree that MSCs reside in these mesenchymal tissues, the possibility has been raised that a long-distance traffic of MSCs occurs between the bone marrow and distant sites, through the bloodstream. Alternatively, embryonic primordia of MSCs may be stored in organs of mesodermal origin and, in response to injury, may participate in tissue repair (Pittenger and Martin, 2004).

During the phase of amplification, MSCs do not differentiate spontaneously but do so in the presence of growth factors and cytokines. They can acquire multiple phenotypes, including osteoblasts, chondrocytes, adipocytes, endothelial cells, and neuronal-like cells. Bone marrow MSCs differentiate into cardiomyocytes in the presence of 5-aza-cytidine (Makino *et al.*, 1999); the morphology of the cells changes from a spindle shape to a ball-like form and, subsequently, a rod-shaped configuration. The cells then fuse in a syncytiumlike structure that resembles a myotube. Although these characteristics mimic the organization of skeletal muscle cells, the committed progeny expresses markers commonly found in cardiomyocytes at different stages of fetal development (Makino *et al.*, 1999).

At the end of the 1990s, following transplantation in irradiated animals, MSCs durably engrafted in bone, cartilage, and lungs of mice (Pereira *et al.*, 1998), giving rise to fibroblast-like cells that could be reisolated and cultured from the lungs, calvaria, cartilage, long bones, tails, and

skin. The presence of MSCs has been demonstrated in many tissues other than the bone marrow. The clear identification of MSCs is complicated by the fact that definitive *in vivo* markers are still lacking. Retrospective functional data strongly support the existence of common adult stem cells in mesenchymal tissues that have the capacity to differentiate along various specific differentiation lineages. Because MSCs are multipotent and can easily be expanded in culture, there has been much interest in their clinical potential for tissue repair and gene therapy. And numerous studies have been carried out demonstrating the migration and multiorgan engraftment potential of MSCs in animal models and in humans. However, understanding the mechanisms behind MSC cell fate determination is not easy, because the molecular processes that drive engraftment and differentiation are complex.

### Cardiac Stem Cells

As occurred for the central nervous system, an organ considered irreversibly terminally differentiated, CSCs have been isolated from the adult myocardium, and long-term cultures have been developed (Beltrami *et al.*, 2003). Subsequently, data collected in 10 distinct laboratories concur with the concept that primitive cells reside in the adult mammalian heart. However, disagreement exists concerning the surface phenotype of CPCs, their number, and their functional characteristics. A direct comparison of the *in vitro* and *in vivo* behavior of the distinct CPC subsets has not been performed yet, making difficult the interpretation of these recent findings. The different populations of CPCs may represent independent categories of cardiac primitive cells. If this were the case, the heart, in analogy with the bone marrow, could contain several compartments of stem cells. Alternatively, the same cellular compartment has been analyzed with noncomparable approaches and methodologies, and the apparent multiple CPC populations correspond to stages of maturation/differentiation of the same original cell. Thus, the postulated differences in CPC classes reflect stages of a common stem cell pool.

The first study focused on lineage-negative ( $\text{Lin}^-$ )  $\text{c-kit}^{\text{POS}}$  cells, which were shown to have the components of stemness: self-renewal, clonogenicity, and multipotentiality (Beltrami *et al.*, 2003). Similar *in vitro* properties characterize cardiac cells that express MDR1 or Sca-1 only (Linke *et al.*, 2005). However, most primitive cardiac cells possess the three antigens together, and only a small percentage expresses only c-kit, MDR1, or Sca-1. *In vitro*,  $\text{Lin}^- \text{c-kit}^{\text{POS}}$  cells grow as an adherent monolayer when seeded in dishes or form spheroids when in suspension, mimicking the biology of neural stem cells (Tropepe *et al.*, 1999). *In vivo*, CSCs implanted in the infarcted ventricle (Beltrami *et al.*, 2003) or mobilized to the dead myocardium (Urbanek *et al.*, 2005) migrate, engraft, undergo multilineage commitment, and promote cardiac regeneration (Fig. 37.3). Reports in mice, rats, dogs, and humans indicate that there is one

**FIG. 37.3.** Myocardial repair. Section of an infarcted rat myocardium at one month after coronary artery occlusion and implantation of clonogenic c-kit-positive cardiac stem cells. A band of regenerating myocardium is indicated by arrowheads. Newly formed myocytes are recognized by the red fluorescence of  $\alpha$ -sarcomeric actin and green fluorescence of BrdU, which was administered after the injection of stem cells.

$\text{Lin}^- \text{c-kit}^{\text{POS}}$  stem cell per ~8,000–20,000 myocytes, or ~32,000–80,000 cardiac cells (Anversa *et al.*, 2006). This frequency is similar to that reported for HSCs in the bone marrow. However, some investigators have reported that primitive cells represent 2% of all cells, i.e., 2 per ~25 myocytes, or ~100 cardiac cells (Oh *et al.*, 2003). This high value may include some endothelial progenitors, which are lineage-committed Sca-1<sup>POS</sup> cells.

The side population (SP) cells were first identified in the bone marrow (Goodell *et al.*, 1996). SP cells are characterized by their intrinsic capacity to efflux Hoechst dye through an ATP-binding cassette transporter. The bone marrow SP can be further subdivided in the upper side fraction that contains  $\text{Lin}^- \text{CD34}^{\text{POS}}$  cells and the lower side fraction that

is composed of KSL cells which are Lin<sup>-</sup>c-kit<sup>POS</sup>-Sca-1<sup>POS</sup> (Robinson *et al.*, 2005). SP cells have been shown to exist in multiple tissues and are capable of tissue-specific differentiation. A cardiac SP cell population has been found in the adult and developing heart. These putative CSCs are 93% Sca-1<sup>POS</sup> and represent a subset, 1 per ~10,000 cells, of the 2% Sca-1-positive cells in the mouse heart (Pfister *et al.*, 2005). According to a different study, however, SP cells comprise 2% of all cells (2 per ~100 cardiac cells), express CD31, and form hematopoietic colonies *in vitro* (Martin *et al.*, 2004). The presence of CD31 and the peculiar growth behavior of these cells *in vitro* suggest that these cells could originate from the bone marrow and may include endothelial progenitors, raising doubts about the existence of a resident SP in the heart.

Recently, however, attention has been focused on a subset of the SP cells. This cell fraction retains the ability to exclude the Hoechst 33342 dye and express Sca-1 but is negative for CD31 (Pfister *et al.*, 2005). The modest expression of c-kit in these cells was attributed to methodological limitations inherent in the enzymatic cleavage of this receptor during digestion of the myocardium and cell isolation. The frequency of these cells in the myocardium is consistent with that found in other adult self-renewing organs. In fact, there is one SP cell per ~30,000 cardiac cells in the mouse heart. Importantly, CD31<sup>-</sup> cardiac SP cells acquire the molecular and functional characteristics of adult myocytes. When cocultured with differentiated cardiomyocytes, SP-derived cells express cardiomyocyte-specific transcription factors and contractile proteins and, upon stimulation, exhibit calcium transients and contractile activity (Pfister *et al.*, 2005).

A distinct subset of the cardiac SP was found to form clonal spheroids in serum-free medium. In addition to the multidrug resistance transporter gene, these cells expressed nestin and Musashi-1, which are markers of undifferentiated neural precursor cells (Tomita *et al.*, 2005). After transplantation into chick embryos, nestin<sup>POS</sup>-Musashi<sup>POS</sup> cells undergo differentiation into cardiomyocytes. Importantly, undifferentiated and differentiated neural crest-derived cells are present in the fetal myocardium. In the adult heart, these cells have the features of stem cells: They are quiescent and multipotent, giving rise to myocytes and typical neural crest-derived cells, including neurons, glia, and smooth muscle.

Surprisingly, Isl1-positive cells have been alleged to correspond to the “true” cardiac stem cell, with important implications in myocardial regeneration of the failing human heart (Laugwitz *et al.*, 2005). Isl1-positive cells are neither self-renewing nor clonogenic or multipotent, lacking the indispensable elements of stem cells. Isl1-positive cells are undetectable in the atrial and ventricular myocardium of the adult mouse and rat heart or in the decompensated human heart. Even during development, Isl1 cells are not implicated in the formation of the left ventricle (Cai *et al.*,

2003), whose deterioration in the adult is the predominant cause of heart failure and death in the patient population. Whether direct activation, local implantation, or systemic mobilization of Isl1-positive cells can repair the infarcted heart remains to be shown. The lack of this information questions the therapeutic import, if any, of this immature myocyte.

## V. THE EMBRYO AS A MODEL OF PROGENITOR CELL ENGRAFTMENT AND PLASTICITY

Tissue injury is an essential aspect of successful cell engraftment, activation, and differentiation (Lapidot *et al.*, 2005). Therefore, the vast majority of the transplantation assays aiming at the documentation of the *in vivo* properties of progenitor cell populations has been performed in pathological models mimicking human cardiac diseases. However, the possibility has been raised that the capacity of stem cells to differentiate or transdifferentiate into parenchymal cells may be a nonphysiological artificial process. If this were the case, the behavior of stem cells would be entirely dictated by the unusual cytokine profile and extracellular matrix alterations present at the site of injury and would not reflect inherent features of the primitive cells. When stem cells fail to engraft and differentiate in intact organs and the results obtained in injured organs cannot be reproduced under physiological conditions, the artful nature of stem cell-mediated tissue repair seems to be confirmed. In these studies, the fact that the administered cells are at a growth disadvantage with respect to resident progenitors was not taken into account. Thus, it should not have been surprising that the implanted cells did not contribute significantly to physiological turnover and tissue homeostasis.

The embryo offers the unique opportunity to assess the behavior of progenitor cells in noninjured tissues and organs. Because of the multiple environmental cues that greatly favor cell growth and proliferation in embryos, the long-term engraftment of primitive cells is facilitated. Although the rapid pace at which cells renew themselves prenatally is not identical to the slow cell turnover in the postnatal heart, brain, or skeletal muscle, the intrinsic properties of progenitor cells may be better characterized when tissue damage is absent, such as during embryogenesis. Upon homing in embryonic and fetal tissues, adult progenitor cells can undergo growth and differentiation and actively participate in organ formation. Organogenesis involves the specification of primitive cell populations and the acquisition of specific fates. This process engages progenitor cells that reside at the embryonic site where the organ develops as well as migrating neighboring or circulating undifferentiated cells. The administered adult stem cells may colonize all organs or home preferentially to the organ from which they have been obtained or to a group of organs of the germ layer to which they belong. By this approach, the capacity

of progenitor cells to form a progeny identical to or different from the organ of origin can be established. The generation of cells of unexpected lineage corresponds to transdifferentiation or stem cell plasticity, and, if a class of progenitor cells exhibits developmental plasticity in prenatal life, the possibility exists that this growth-and-differentiation characteristic is maintained in the adult.

An additional critical question is whether cardiac repair after injury recapitulates the developmental steps that occur in the embryonic heart. The unraveling of the molecular signaling pathways regulating the complex steps of embryonic heart formation is fundamental, in view of the option to manipulate progenitor cells genetically prior to their transplantation within the damaged myocardium. This information may help our understanding of the behavior of resident progenitor cells in response to pathologic states and their ability to initiate a repair process. The reactivation of the fetal gene program has been documented in the hypertrophic and failing heart. An extensively studied phenomenon is the switch of the myosin heavy-chain gene from the  $\alpha$ -isoform, which is typical of the adult heart, to the  $\beta$ -isoform, which is highly expressed in the embryonic-fetal and neonatal heart (Tardiff *et al.*, 2000). Because the heart was viewed as a postmitotic organ, the possibility that activation of resident progenitor cells might lead to enhanced formation of amplifying myocytes has been ignored. This process may involve the identical spatial and temporal expression of the genes implicated in myocyte formation during embryonic maturation of the developing myocardium (Beltrami *et al.*, 2003). Thus, the expression of  $\beta$ -myosin may be part of the progressive acquisition of the adult phenotype by stem cell-derived myocytes.

Although primitive cells are present in the heart early in embryonic life and regulate heart morphogenesis and postnatal development, the properties of these primitive cells are still controversial. The hypothesis has been advanced that multiple unipotent progenitors give rise to distinct classes of myocytes that populate different regions of the heart: atria, outflow tract, and left and right ventricles (Mikawa and Fishman, 1996). Recently, the likelihood that a common precursor segregates into two lineages of myocytes has been raised (Meilhac *et al.*, 2004a). According to this theory, the primitive left ventricle and the outflow tract are derived from a single cell lineage, while all other regions of the heart, including the primitive atria and the right ventricle, are colonized by both lineages. This view is supported by the differential expression of the transcription factors Nkx2.5, Tbx5, Isl1, eHAND, and dHAND in distinct cardiac regions (Pandur, 2005).

The early common origin of cardiomyocytes has been recognized by utilizing a novel approach that involved the retrospective clonal analysis of the cells composing the mouse embryonic heart. Clones of developing myocytes derived from multiple precursors appear on different days of embryonic development and in distinct morphogenetic

regions but show a uniform genetic background. This characteristic documents their derivation from a shared pool of founder cells. These precursors account for ~140 cells at E8.5 and give rise to the whole heart tube in its entire length (Meilhac *et al.*, 2003, 2004a, 2004b). The initiation of separate transcriptional programs in the cells of the cardiac chambers is not the consequence of a diverse clonal origin from unipotent progenitors but a process that occurs later in development. This pattern of myocardial histogenesis has been confirmed by introducing the EGFP gene in the embryo at the very early stage of the morula–blastocyst transition. EGFP was placed under the control of the desmin or  $\alpha$ -cardiac actin promoter, leading to the accumulation of EGFP in all cells that express these myocyte-specific proteins.

A similar strategy was employed to study the pattern of clonal myocyte distribution during heart development and to document the existence of an individual intracardiac common progenitor of cardiomyocytes in prenatal and postnatal life (Ebherard and Jockusch, 2005). Two eight-cell morulas were combined, giving rise to a chimeric morula that evolves into a chimeric blastocyst. Since the two morulas carried either the LacZ or EGFP transgene under the control of the desmin promoter, the different genetic origin of the developing myocytes could be studied by labeling techniques. Early chimeric blastocysts were implanted in pseudo-pregnant mice. This approach, termed the *aggregation method*, allows the determination of the number of progenitor cells that contributes to the development of the heart or other organs. The distribution of the progeny of the precursors may result in balanced or unbalanced mouse chimeras, which correspond to equal or unequal parental contribution, respectively.

Tissue sections obtained from the embryonic and adult heart of these chimeric mice were analyzed, and patchy areas of labeling were quantified. The presence of “holes,” or nonlabeled areas, in the patches was also determined. The distribution of labeled areas did not change as a function of age, and it was dictated by a mechanism of coherent expansion of clones. In this case, patchy areas of the heart are  $\beta$ -gal-positive and others EGFP positive. However, limited intermingling of clonogenic cells occurs, and small foci of  $\beta$ -gal-positive cells are found in EGFP clonal patches, or vice versa. The possibility that this model of cardiac growth is mediated by a large number of progenitors would require a massive loss of clones early in development, a phenomenon that cannot be excluded. If thousands of progenitors were implicated in embryonic cardiac growth, a mechanism of coherent expansion together with extensive intermingling of clonogenic cells would lead to a dispersed pattern of cardiomyocyte formation. Importantly, the persistence of the embryonic clonal patches with small, intermingled foci in the adult myocardium excludes that new clonal regions contribute to the growth of the heart postnatally (Ebherard and Jockusch, 2005).

The view of the developing heart as an organ originated exclusively from the expansion of the cardiomyocyte precursors of the two paired mesodermal fields is a matter of debate (Eisenberg and Eisenberg, 2004). Evidence collected recently indicates that only a portion of the contractile muscle in the mature heart descends from this primordial myocardial tissue. Cells that reside in neighboring nonmuscle tissue or migrate to the myocardium from distant sites through the circulation participate in the growth of the cardiac muscle (Eisenberg *et al.*, 2003). Whether this multiplicity of events is recapitulated in the postnatal heart is unknown, but it suggests the possibility that exogenous progenitor cells may maintain a certain degree of plasticity in adult life.

The integration of blood-borne cells in the developing heart has been documented in a model of parabiosis between quail and chicken (Sedmera *et al.*, 2006). The formation of a common circulatory system occurs at embryonic day 15, and cells of quail origin are found in multiple tissues of the chick embryo. Circulating cells differentiate into vascular ECs and SMCs and cardiomyocytes. This process is the result of transdifferentiation; fusion of quail and chick cells is an extremely rare event. Similar results are obtained when adult bone marrow cells are coincubated with embryonic heart. In a manner comparable to the HSCs, the ability of human MSCs to contribute to organ growth and turnover has been investigated. The model of the fetal sheep has been employed because this animal is immunologically tolerant before 75 days of gestation and chimeric human–sheep organs can be formed without rejection and the need of immunosuppressive therapy. Moreover, the large difference between human and sheep antigens allows the unequivocal identification of the origin of cells and

tissue structures. After transplantation in the fetal peritoneal cavity, MSCs traverse the endothelial barrier and engraft in nearly all tissues of the organism (Liechty *et al.*, 2000). MSCs gave rise to multiple parenchymal cell types belonging to the ectodermal and mesodermal germ layers. Human cells have been found in the pulmonary epithelia, thymic epithelia, skin wounds, and perivascular regions of the central nervous system. Skeletal and cardiac muscle were among the nonlymphohemopoietic and mesodermal organs that were colonized by human MSCs. In the heart, cells positive for the Alu probe and SERCA-2 protein were identified, documenting the presence of human myocytes in the sheep heart. Cardiomyocytes derived predominantly from transdifferentiation of human MSCs, although scattered myocytes with human nucleus and sheep cytoplasm were seen. MSCs have long-term engraftment potential and maintain multipotentiality upon transplantation, representing good candidates for cellular and gene therapy applications.

## VI. CONCLUSIONS

This chapter has analyzed the different progenitor cell classes that are capable of differentiating into cardiomyocytes and coronary vessels in the adult heart. The recognition that HSCs and MSCs possess the ability to form myocardial tissue has significant clinical implications and supports the notion of stem cell plasticity in the adult organs and organism. The recent identification of CSCs, which are self-renewing, clonogenic, and multipotent *in vitro* and regenerate infarcted myocardium *in vivo* extends the possibility of implementing HSCs, MSCs, and CSCs in the treatment of cardiac failure of ischemic and nonischemic origin. However, the search for the most appropriate progenitor cell for cardiac repair continues.

### I. INTRODUCTION

Heart disease remains the leading cause of death in developed countries. Tissue engineering offers a potential to grow *in vitro* functional equivalents of native myocardium for use in tissue repair and to investigate new ways to treat or prevent the disease. In this chapter, we focus on a tissue-engineering approach to the generation of a functional cardiac patch. In the first part, we review the clinical problem and the requirements for the tissue engineering of a functional cardiac patch in a form suitable for surgical implantation. In the second part, we give an overview of the representative most significant research in cardiac tissue engineering:

1. The biomimetic approach through the integrated use of cells, scaffolds, and bioreactors.
2. The mechanical stimulation of cardiomyocytes embedded in the collagen gels.
3. The cell-sheet approach.

We then describe in more detail the biomimetic approach to tissue engineering, where the tissue-engineering approach is designed to mimic the main factors present in the native myocardium: high cell density with multiple cell types, convective-diffusive oxygen transport through a capillary network, and excitation-contraction coupling. Finally, we discuss some of the current challenges and research needs.

### II. CLINICAL PROBLEM

Cardiovascular disease is responsible for a preponderance of health problems in the developed countries as well as in many developing countries. Heart disease and stroke, the principal components of cardiovascular disease, are, respectively, the first and the third leading cause of death in the United States, accounting for nearly 40% of all deaths. Congenital heart defects, which occur in nearly 14 of every 1000 newborn children (Gillum, 1994), are the most common congenital defects and the leading cause of death in the first year of life. Cardiovascular diseases result in substantial disability and loss of productivity and contribute significantly to the escalating costs of health care. About 70 million Americans (almost one-fourth of the population) live with cardiovascular diseases, such as coronary heart disease, congenital cardiovascular defects, and congestive heart failure, and result in an economic burden of around \$300 billion per year to treat these diseases ([www.americanheart.org/presenter.jhtml?identifier=4478](http://www.americanheart.org/presenter.jhtml?identifier=4478)). The economic impact of cardiovascular disease is expected to grow further as the population ages.

Conventional therapies are limited by the inability of myocardium to regenerate after injury (Soonpaa and Field, 1998) and by the shortage of organs available for transplantation. For those reasons, cell-based therapies have been

considered a novel and potentially curative treatment option (Reinlib and Field, 2000), either by utilization of cells alone (Koh *et al.*, 1993; Soonpaa *et al.*, 1994; Li *et al.*, 1996; Taylor *et al.*, 1998; Reinecke *et al.*, 1999; Sakai *et al.*, 1999; Condorelli *et al.*, 2001; Etzion *et al.*, 2001; Menasche *et al.*, 2001; Orlic *et al.*, 2001; Muller-Ehmsen *et al.*, 2002a, 2002b; Roell *et al.*, 2002; Laflamme and Murry, 2005) or by tissue engineering of cardiac grafts *in vitro* that can be surgically attached to the myocardium (Eschenhagen *et al.*, 1997; Akins *et al.*, 1999; Bursac *et al.*, 1999; Carrier *et al.*, 1999; Li *et al.*, 1999; Fink *et al.*, 2000; Leor *et al.*, 2000; Li *et al.*, 2000a; Papadaki *et al.*, 2001; Kofidis *et al.*, 2002; Shimizu *et al.*, 2002; Zimmermann *et al.*, 2002a, 2002b; Radisic *et al.*, 2003, 2004c). We believe that both treatment options are viable and that the appropriate choice will depend on time postinfarction.

Upon myocardial infarction, a vigorous inflammatory response is elicited, and dead cells are removed by marrow-derived macrophages. Over the subsequent weeks to months, fibroblasts and endothelial cells proliferate, forming granulation tissue that ultimately becomes a dense collagenous scar. Formation of scar tissue severely reduces contractile function of the myocardium and leads to ventricle wall thinning and dilatation, remodeling of the heart wall, and ultimately heart failure. The regeneration strategy thus depends on the time postinfarction; i.e., new and old infarcts most likely cannot be treated via the same approach.

Cell injection strategies will work best if applied shortly after myocardial infarction (MI). Application of cells and growth factors within hours and days after MI has a potential of directing the wound-repair process so that the minimum amount of scar tissue is formed, the contractile function is maintained in the border zone, and pathological remodeling is attenuated. Tissue-engineering strategies will work in the acute phase as well, but they may be more necessary after scar has formed. Then larger areas of heart must be replaced or augmented, and this is potentially where a scaffold-based approach may be most useful.

### III. PROBLEM DEFINITION

#### The Myocardium

The myocardium is a highly differentiated tissue, 1.3–1.6 cm thick in humans, composed of cardiac myocytes and fibroblasts with a dense supporting vasculature and collagen-based extracellular matrix. Cardiac myocytes form a three-dimensional syncytium that enables propagation of electrical signals across specialized intracellular junctions to produce coordinated mechanical contractions that pump blood forward (Severs, 2000). Only 20–40% of the cells in the heart are cardiac myocytes, but they occupy 80–90% of the heart volume. The average cell density in the native rat myocardium is on the order of  $5 \cdot 10^8$  cells/cm<sup>3</sup>. Morphologically, intact cardiac myocytes have an elongated, rod-shaped appearance. The contractile apparatus of cardiac myocytes consists of sarcomeres arranged in parallel myofibrils. The

high metabolic activity of cardiac myocytes is supported by the high density of mitochondria. Electrical signal propagation is provided by specialized intercellular connections, gap junctions (Severs, 2000).

The control of heart contractions is almost entirely self-contained. Groups of specialized cardiac myocytes (pacemakers), the fastest of which are located in the sinoatrial node, drive periodic contractions of the heart. The majority of the cells in the myocardium are nonpacemaker cells, and they respond to the electrical stimuli generated by pacemaker cells. Excitation of each cardiac myocyte is followed by an increase in the amount of cytoplasmic calcium that triggers mechanical contraction. The propagation of the electrical excitation through the tissue by ion currents in the extracellular and in the intercellular space results in synchronous contractions that enable the pumping of blood from the heart.

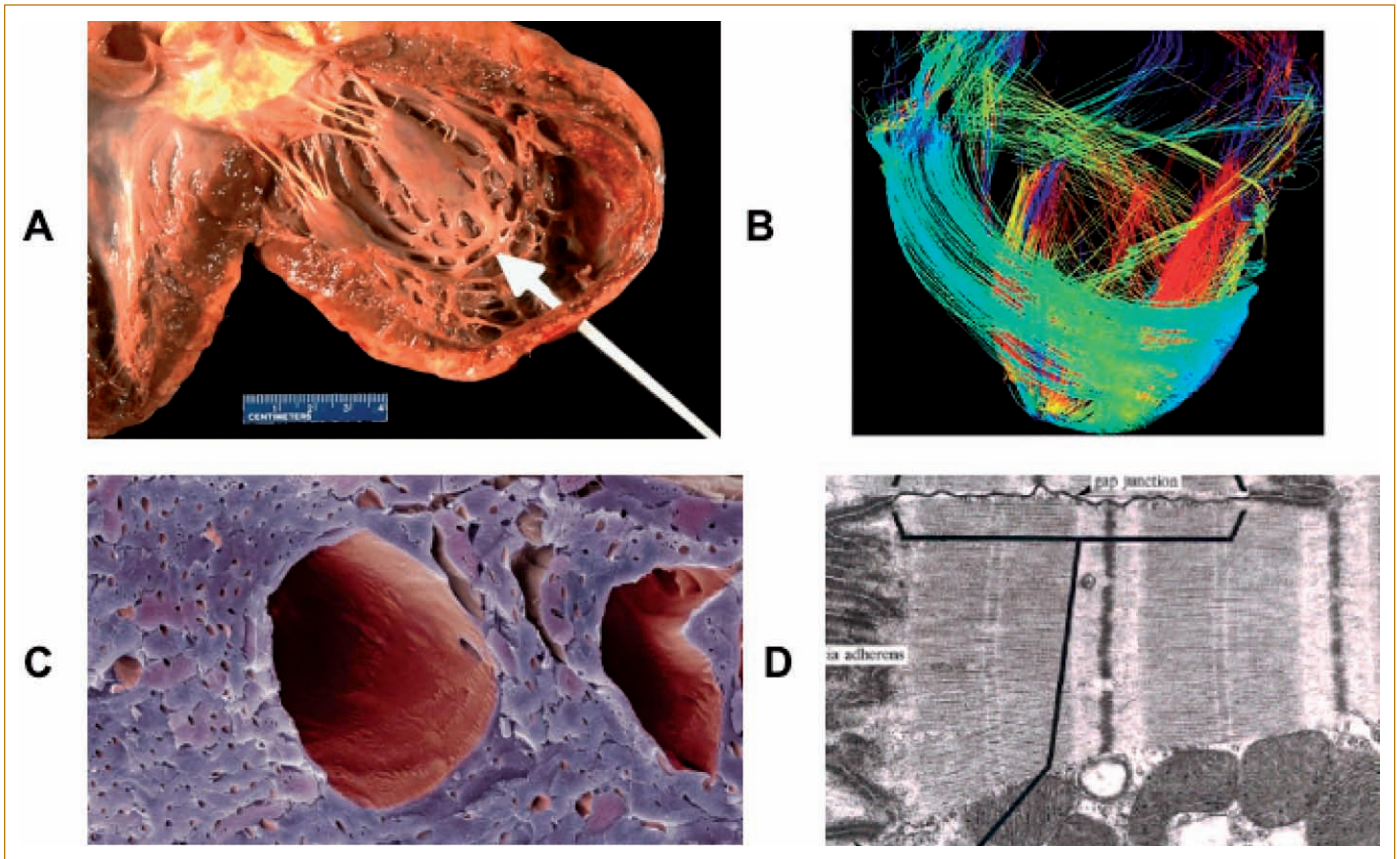

#### Requirements for a Functional Cardiac Patch

In order to provide a functional cardiac patch, tissue-engineering approaches must accurately mimic the structure of native myocardium over several different length scales. At the centimeter scale, tissue engineering should yield a mechanically stable construct of clinically relevant thickness, comparable to the thickness of the human myocardium (~1.5 cm) (Fig. 38.1A). This requirement is hampered by the diffusional limitations of the oxygen supply encountered in most tissue culture vessels, coupled with the high metabolic demand of cardiomyocytes for oxygen (27.6 nmol/mg protein/min; Yamada *et al.*, 1985).

At the millimeter scale, the tissue should consist of elongated myofibers aligned in parallel, with the angle changing along the thickness of the ventricle and capable of synchronous contractions, a requirement that is hampered by our ability to provide appropriate electromechanical stimulation during culture (Fig. 38.1B). At the micrometer scale, the tissue should consist of high-cell-density myocytes (~ $10^8$  cells/cm<sup>3</sup>) supported by a rich vasculature, with intercapillary distances of ~20  $\mu$ m (Fig. 38.1C) (Rakusan and Korecky, 1982). At the nanometer scale, cells in the engineered cardiac tissue must be coupled by functional gap junctions and capable of propagating electrical impulses in order to prevent arrhythmia upon implantation. Finally, at the subcellular level, the excitation–contraction machinery of individual cardiomyocytes must be functional (Fig. 38.1D).

#### Clinically Relevant Cell Sources

The major limitation in the progress of cardiac-tissue engineering toward clinical applications, via either the cardiac patch or drug testing, is the lack of an appropriate human cell source. Adult cardiac myocytes are terminally differentiated and have no ability to proliferate (Soonpaa and Field, 1998); thus they cannot be utilized as a source of autologous cells for tissue engineering. Cardiac myocytes

**FIG. 38.1.** Requirements for a functional cardiac patch. In order to provide appropriate function, the patch must satisfy structural requirements at different length scales: **(A)** thickness of 1.5 cm (Florida State University, The Internet Pathology Laboratory for Medical Education, <http://www-medlib.med.utah.edu/WebPath/CVHTML/CV126.html>); **(B)** appropriate myofiber orientation at the millimeter scale with permission from Helm *et al.* (2005); **(C)** high cell density and rich vasculature at the micrometer scale with permission from Zandonella (2003); and **(D)** functional excitation–contraction coupling pathway at the nanometer scale with permission from Severs (2000).

can be obtained in potentially unlimited quantities and at high purity from embryonic stem cells (Klug *et al.*, 1996; Zandstra *et al.*, 2003). However, nuclear transfer is required to make them autologous, and the presence of undifferentiated cells may lead to teratomas upon implantation (Laflamme and Murry, 2005). Recent studies report cultivation (Alperin *et al.*, 2005; Guo *et al.*, 2006) and implantation (Guo *et al.*, 2006) of cardiac grafts based on mouse embryonic stem cells.

Mesenchymal stem cells (MSC) from bone marrow (Makino *et al.*, 1999) or liposuction aspirates (Planat-Benard *et al.*, 2004) were reported to differentiate into cardiomyocytes *in vitro*. Transplantation of cell sheets based on adipose tissue–derived mesenchymal stem cells was demonstrated to improve contractile function in a rat model of coronary artery ligation (Miyahara *et al.*, 2006). It is thought that a small fraction of MSC differentiating into cardiomyocytes and newly formed blood vessels may contribute to the improvement in function.

Recent emerging work suggests that the heart may contain resident progenitor cells. This is an exciting possi-

bility, for resident progenitor cells may be an ideal source of autologous cardiomyocytes. However, it appears that there is more than one heart cell subpopulation that fits the description of a cardiac progenitor. *c-kit*<sup>+</sup> cells isolated from adult rat hearts and expanded under limited dilution gave rise to cardiomyocytes, smooth muscle, and endothelial cells when injected into ischemic myocardium (Beltrami *et al.*, 2003). Oh *et al.* (2003) reported Sca-1 as a marker of resident cardiac progenitors and expression of cardiac markers upon treatment with 5-azacytidine. LIM homeodomain islet 1 (*isl1*<sup>+</sup>) was also identified as a marker of resident cardiac progenitor cells (Laugwitz *et al.*, 2005). The *isl1*<sup>+</sup> cells from mouse hearts were propagated in culture, and they differentiated into functional cardiac myocytes when in contact with terminally differentiated cardiomyocytes.

It remains to be seen if the progenitors, regardless of their marker, can be isolated from adult human biopsies and if sufficient numbers of cardiomyocytes ( $>10^8$  cells/patient/patch) can be generated *in vitro*. Most of the current work in cardiac-tissue engineering is still performed with neonatal rat cardiomyocytes.

## IV. PREVIOUS WORK

Cardiac-tissue constructs that express structural and physiological features characteristic of native cardiac muscle have been engineered using rat cardiac myocytes cultured in collagen gels with mechanical stimulation (Eschenhagen *et al.*, 1997; Fink *et al.*, 2000; Zimmermann *et al.*, 2000, 2002b), on collagen fibers (Akins *et al.*, 1999), on synthetic fibrous scaffolds (Bursac *et al.*, 1999; Carrier *et al.*, 1999; Papadaki *et al.*, 2001; Carrier *et al.*, 2002a, 2002b), and on porous collagen scaffolds (Li *et al.*, 1999, 2000b; Radisic *et al.*, 2003). Culture systems included constructs cultured statically in well plates (Carrier *et al.*, 1999; Li *et al.*, 1999; Leor *et al.*, 2000; Papadaki *et al.*, 2001; Radisic *et al.*, 2003), exposed to mixed fluid in magnetically stirred flasks (Bursac *et al.*, 1999; Carrier *et al.*, 1999; Papadaki *et al.*, 2001), and freely suspended in convective flow in rotating bioreactor vessels (Akins *et al.*, 1999; Carrier *et al.*, 1999; Papadaki *et al.*, 2001). Transport of oxygen, carbon dioxide, nutrients, and metabolites to and from the cells was enhanced by convection at construct surfaces, but it was governed by molecular diffusion within the tissue constructs. At physiologic cell densities, oxygen transport by diffusion can support cell viability in only an ~100- $\mu\text{m}$ -thick layer in contact with culture medium, but not in the construct interior, which remains largely acellular (Bursac *et al.*, 1999; Carrier *et al.*, 1999; Zimmermann *et al.*, 2000; Papadaki *et al.*, 2001). In most of these early systems, the main physical stimulus was the hydrodynamic shear associated with fluid flow that enhanced the rate of mass transport but — if excessive — could adversely affect the cells (Bursac *et al.*, 1999; Carrier *et al.*, 1999).

### Application of Cyclic Mechanical Stretch to Neonatal Rat Heart Cells in Collagen

Matrigel significantly improved the level of cell differentiation and the force of contraction, but some hallmarks of cardiac differentiation were still missing (including M bands and IC discs) (Zimmermann *et al.*, 2002b), and the distribution and frequency of gap junctions, critical for electrical signal propagation in the tissue, remained unclear. It appeared that the excitation–contraction coupling has not been fully established. More recent studies by the same group, discussed later in detail, have shown that multiple constructs engineered using this method and overlaid into a star-shaped structure, can be implanted on infarcted rat hearts, where it integrates with the host tissue and results in substantial improvement of the structural and functional properties of the grafted area (Zimmermann *et al.*, 2006).

Clinically sized ( $6 \times 8 \times 2$  mm thick), compact cardiac constructs with physiologic cell densities were engineered *in vitro* by mimicking various aspects of the *in vivo* environment in native myocardium, including the oxygen supply by perfusion of culture medium supplemented with oxygen carriers (Radisic *et al.*, 2005) and the induction of construct

contractions by electrical pacing signals (Radisic *et al.*, 2004a).

## V. BIOMIMETIC APPROACH TO CARDIAC-TISSUE ENGINEERING

We describe here in detail the “biomimetic” approach we have developed for cardiac-tissue engineering. The approach involves the *in vitro* creation of immature but functional tissues by an integrated use of: (1) *differentiated cells*, (2) *biomaterial scaffolds* that serve as a structural and logistic template for tissue development and that biodegrade at a controlled rate, and (3) *bioreactors* that provide environmental conditions necessary for the cells to regenerate at a functional tissue.

In this approach, a bioreactor should ideally provide all necessary conditions in the *in vitro* environment for rapid and orderly tissue development by cells cultured on a scaffold. In general, a bioreactor is designed to perform one or more of the following functions: (1) establish a desired spatially uniform cell concentration within the scaffold during cell seeding, (2) maintain controlled conditions in culture medium (e.g., temperature, pH, osmolality, levels of oxygen, nutrients, metabolites, regulatory molecules), (3) facilitate mass transfer, and (4) provide physiologically relevant physical signals (e.g., interstitial fluid flow, shear, pressure, electrical stimuli) during cultivation of cell–polymer constructs. We used the tissue-engineering model system to mimic the major factors present in the native myocardium. We focused on the following key parameters in the cell microenvironment: high cell density with multiple cell types, convective-diffusive oxygen transport through a capillary network, and orderly excitation contraction coupling (Table 38.1).

### Perfusion During Seeding Enabled Physiologic Cell Density

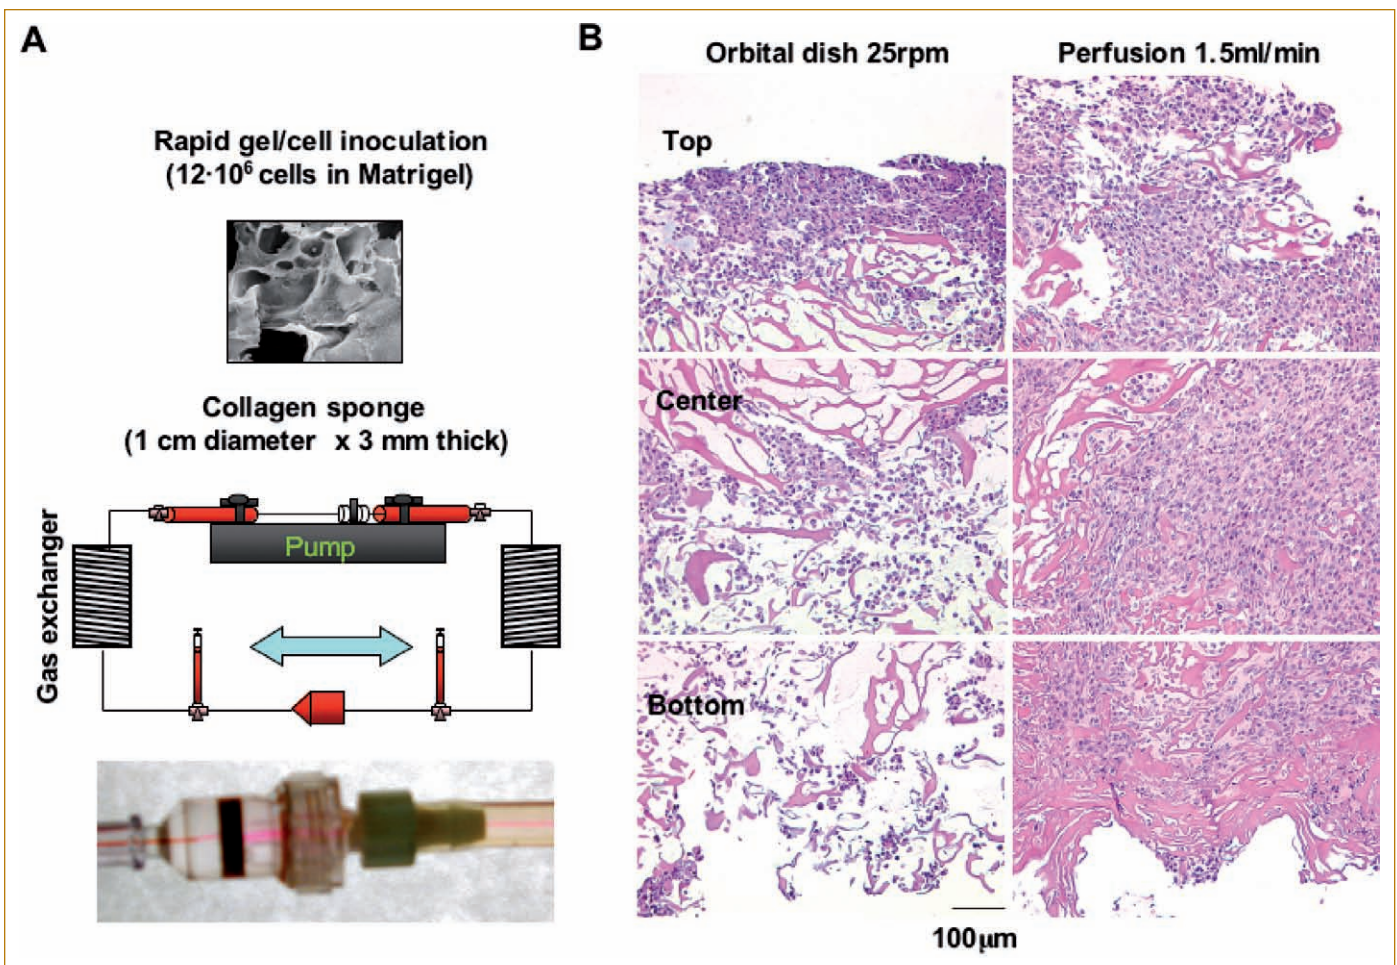

To provide an oxygen supply to the cells at levels necessary to maintain their viability, we developed a technique of seeding that involves (1) rapid cell inoculation into collagen sponges using Matrigel® as a cell delivery vehicle, and (2) transfer of inoculated scaffolds into perfused cartridges, with immediate establishment of the interstitial flow of the culture medium (Fig. 38.2A). Forward–reverse flow was used for the initial period of 1.5–4.5 h in order to further increase the rate and spatial uniformity of cell seeding (Radisic *et al.*, 2003). Unidirectional flow of culture medium was maintained for the duration of cultivation. In this system, cells were “locked” into the scaffold during a short (10 min) gelation period and supplied with oxygen at all times during culture.

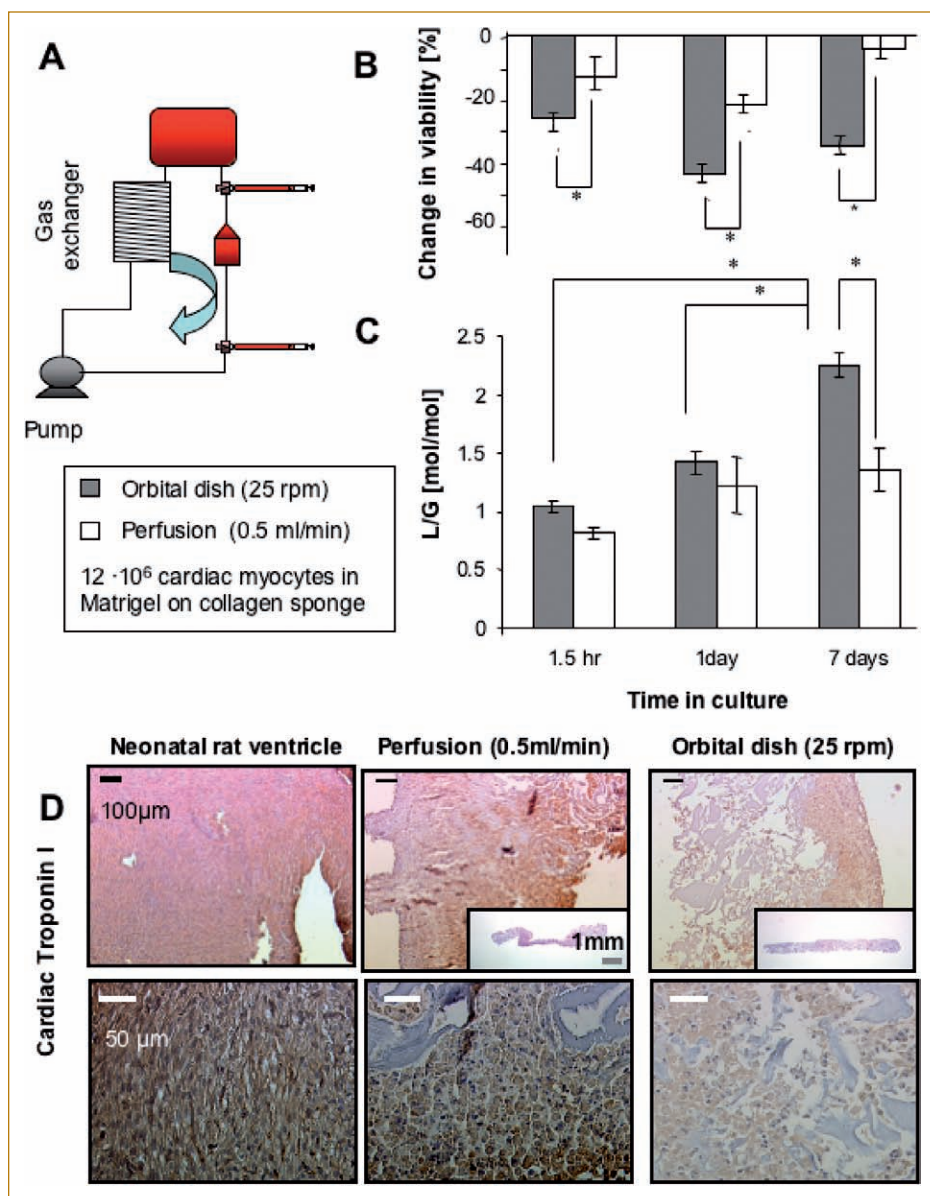

Cell distributions in the top, center, and bottom areas of a 0.65- $\mu\text{m}$ -wide strip extending from one construct surface to the other are shown in Fig. 38.2B. Constructs seeded in dishes had most cells located in the ~100- $\mu\text{m}$ -thick layer at the top surface, and only a small number of

**Table 38.1.** Factors governing cardiac-tissue development *in vitro* and *in vivo*

**FIG. 38.2.** High-density perfusion seeding. **(A)** Cells are rapidly inoculated into collagen sponge using Matrigel and seeded, with alternating flow direction. **(B)** The method results in a spatially uniform distribution of cells at physiologically high concentrations and high cell viability. A full cross section through the center is shown for a construct inoculated with 12 million C2C12 cells and seeded for 4.5 h. Adapted from Radisic *et al.* (2003).

**FIG. 38.3.** Convective-diffusive oxygen transport during culture maintains a high density of viable cells, aerobic cell metabolism, and uniform cell distribution. **(A)** Perfusion loop; **(B)** cell viability; **(C)** cell metabolism; **(D)** distribution of cardiac Troponin I-positive cells. Adapted from Radisic *et al.* (2004c).

cells penetrated the entire construct depth. Constructs seeded in perfusion had high and spatially uniform cell density throughout the perfused volume of the construct. Clearly, medium perfusion during seeding was key for engineering thick constructs with high densities of viable cells, presumably due to enhanced transport of oxygen within the construct.

### Perfusion During Cultivation Enabled Cell Viability and Aerobic Metabolism

Throughout the cultivation, the number of live cells in perfused constructs was significantly higher than in dish-grown constructs, due to the perfusion of culture medium that was equilibrated in each pass with respect to oxygen and pH in an external-loop gas exchanger (Fig. 38.3A).

Notably, the final cell viability in perfused constructs cultured for eight days ( $81.6 \pm 3.7\%$ ) was indistinguishable from the viability of the freshly isolated cells ( $83.8 \pm 2.0\%$ ), and it was markedly higher than the cell viability in dish-grown constructs ( $47.4 \pm 7.8\%$ ) (Radisic *et al.*, 2004c) (Fig. 38.3B). Consistently, the molar ratio of lactate produced to glucose consumed (L/G) was  $\sim 1$  for perfused constructs, indicating aerobic cell metabolism. In contrast, in orbitally mixed dishes, with convective flow of medium around the constructs and molecular diffusion within constructs, L/G increased progressively from 1 to  $\sim 2$ , indicating a transition to anaerobic cell metabolism (Fig. 38.3C). Cell damage, assessed by monitoring the activity of lactate dehydrogenase (LDH) in culture medium, was at all time points significantly lower in perfusion than in dish cultures.

Perfused constructs and native ventricles had more cells in the S phase than in the G2/M phases, whereas the cells from dish-grown constructs appeared unable to complete the cell cycle and accumulated in the G2/M phase. Cells expressing cardiac-specific differentiation markers (sarcomeric  $\alpha$ -actin, sarcomeric tropomyosin, cardiac troponin I) were present throughout the perfused constructs and only within approximately a 100- $\mu$ m-thick surface layer in dish-grown constructs.

Spontaneous contractions were observed in some constructs early in culture and ceased after approximately five days of cultivation, indicating the maturation of engineered tissue. In response to electrical stimulation, perfused constructs contracted synchronously, had lower excitation thresholds, and recovered their baseline function levels following treatment with a gap junction blocker; dish-grown constructs exhibited arrhythmic contractile patterns and failed to recover their baseline levels. However, most cells were round and mononucleated, a situation likely due to the exposure of cardiac myocytes to hydrodynamic shear, in contrast to the native heart muscle, where blood is confined within the capillary bed and therefore not in direct contact with cardiac myocytes (Fig. 38.3D). This motivated the design of scaffolds with arrays of channels that provide a separate compartment for medium flow.

### **In Vivo-Like Oxygen Supply: Medium Perfusion, Channeled Scaffolds, and Oxygen Carriers**

To test the feasibility of using channeled scaffolds, cardiac constructs were first engineered using a channeled collagen scaffold (Ultrafoam™, 1 cm in diameter  $\times$  3 mm thick) seeded with neonatal cardiac myocytes and cultivated in perfusion at 0.5 mL/min for 10 days. The channel maintained its initial diameter and was surrounded with a 300- $\mu$ m-thick tissue layer. However, collagen is not optimal for cardiac-tissue engineering due to its poor structural integrity. We thus explored the use of an elastomer, poly(glycerol sebacate), PGS (Wang *et al.*, 2002), pretreated with neonatal rat cardioblasts for three days in orbitally mixed dishes, followed by the addition of rat cardiomyocytes and perfusion cultivation (Radisic *et al.*, 2006b) (Fig. 38.4A). After only three days of culture, cells on scaffolds formed constructs that contracted synchronously in response to electrical stimulation (Fig. 38.4C). The scaffold pores remained open, and the pressure drop measured across the construct was as low as 0.1 kPa/mm. To mimic the oxygen supply of hemoglobin, culture medium was supplemented by 10% v/v PFC emulsion [Oxygen™, kindly donated by Alliance Pharmaceuticals Corp. (San Diego, CA)]; constructs perfused with unsupplemented culture medium served as controls. Constructs were subjected to unidirectional medium flow at a flow rate of 0.1 mL/min provided by a multichannel peristaltic pump (IsmaTec).

As the medium flowed through the channel array, oxygen was depleted from the aqueous phase of the culture

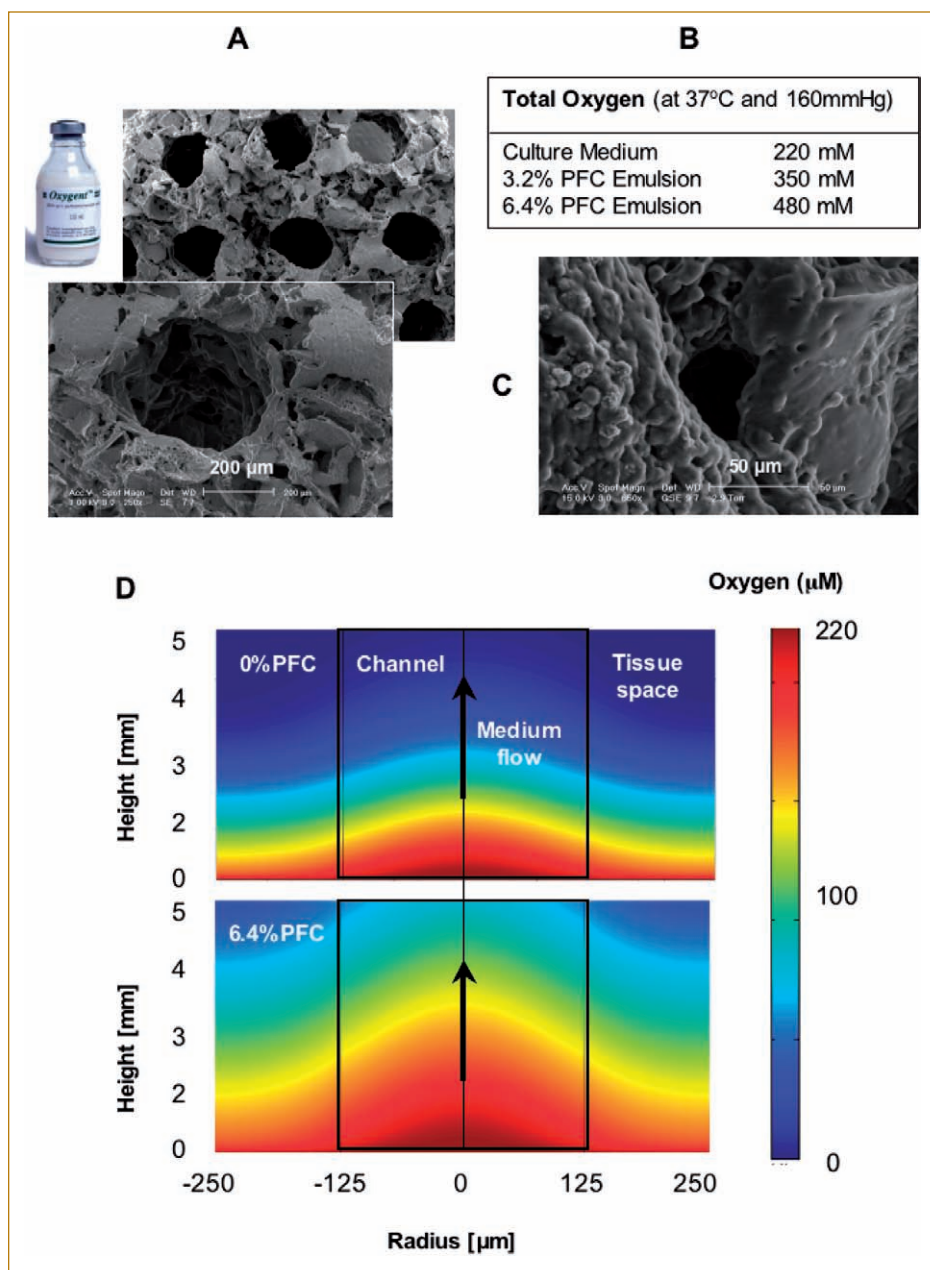

medium by diffusion into the construct space, where it was used for cell respiration. Depletion of oxygen in the aqueous phase acted as a driving force for the diffusion of dissolved oxygen from the PFC particles, thereby contributing to the maintenance of higher oxygen concentrations in the medium. Due to the small size of PFC particles, the passive diffusion of dissolved oxygen from the PFC phase into the aqueous phase was very fast, estimated not to be a rate-limiting step in this system. For comparison, in unsupplemented culture medium, oxygen was depleted faster, since there is no oxygen carrier phase that acts as a reservoir (Fig. 38.4B) (Radisic *et al.*, 2005, 2006a).

In PFC-supplemented medium, the decrease in the partial pressure of oxygen in the aqueous phase was only 50% of that in control medium (28 mmHg vs. 45 mmHg between the construct inlet and outlet at the flow rate of 0.1 mL/min). Consistently, constructs cultivated in the presence of PFC had higher amounts of DNA, troponin I, and Cx-43 and significantly better contractile properties than control constructs. In both groups, cells were present at the channel surfaces as well as within constructs. Improved construct properties were correlated with the enhanced supply of oxygen to the cells within constructs.

In order to rationalize experimental data for oxygen transport and consumption in engineered cardiac constructs with an array of channels, we developed a mathematical model of oxygen distribution in cardiac constructs similar to the Krogh cylinder model. Concentration profiles of oxygen and cells within the constructs were obtained by numerical simulation of the diffusive-convective oxygen transport and its utilization by the cells. The model was used to evaluate the effects of the medium perfusion rate, oxygen carrier, and scaffold geometry on viable cell density (Radisic *et al.*, 2005).

The model was used to define scaffold geometry and flow conditions necessary to cultivate cardiac constructs with clinically relevant thicknesses (5 mm). Oxygen profiles were modeled in a channel array consisting of channels 100  $\mu$ m in diameter and 100  $\mu$ m wall-to-wall spacing at physiologically high cell density  $1 \cdot 10^8$  cells/cm<sup>3</sup>. At 0.049 cm/s, the oxygen concentration increased significantly in both the tissue space and the channel lumen with the increase in circulating PFC emulsion, from 0% to 6.4%. Although the oxygen concentration in the tissue space with physiological cell density increased considerably with the increase of circulating PFC concentration, from 0% to 6.4%, we had to increase the flow rate, keeping the shear stress in the physiological range  $\sim 1$  dyn/cm<sup>2</sup>, in order to provide enough oxygen for the entire 0.5-cm-thick construct. At our best conditions (0.135 cm/s and 6.4% PFC) (Fig. 38.4D), oxygen is not depleted at any point within the tissue construct, and the minimum concentration of 33  $\mu$ M is approximately five times above the  $K_m$  (oxygen concentration at which the consumption rate in the tissue space is maintained at a maximum level) (Radisic *et al.*, 2005).

**FIG. 38.4.** PFC emulsion increases the average oxygen concentration in the channel lumen and tissue space by increasing the oxygen-carrying capacity of the culture medium. **(A)** Channeled scaffolds were seeded with cells and perfused with culture medium that was supplemented with a perfluorocarbon (PFC) emulsion. A scanning electron micrograph (SEM) of a PGS scaffold with laser-bored channel array) is shown at two magnifications, before seeding with cells. **(B)** Supplementation of culture medium with PFC markedly increased the total oxygen content, as shown in table by data measured for two different concentrations of PFC. **(C)** SEM of cardiomyocytes cultured on channeled PGS scaffold perfused with PFC-supplemented culture medium. **(D)** Mathematical model of oxygen distribution in a perfused channeled scaffold with physiological cell density ( $10^8$  cells/cm<sup>3</sup>) in the tissue space. Data are shown for the superficial flow velocity of culture medium of 0.135 cm/s, for cultivations with unsupplemented culture medium (top image), and culture medium supplemented with 6.4% (vol/vol) of PFC (bottom image). Tissue constructs had channels that were 250  $\mu\text{m}$  in diameter, spaced at 250  $\mu\text{m}$  (wall-to-wall distance). Oxygen concentrations in the channel (outlined by a box in the center) and tissue space (on the sides) are shown by color code (on the right). Adapted from Radisic *et al.* (2005, 2006c).

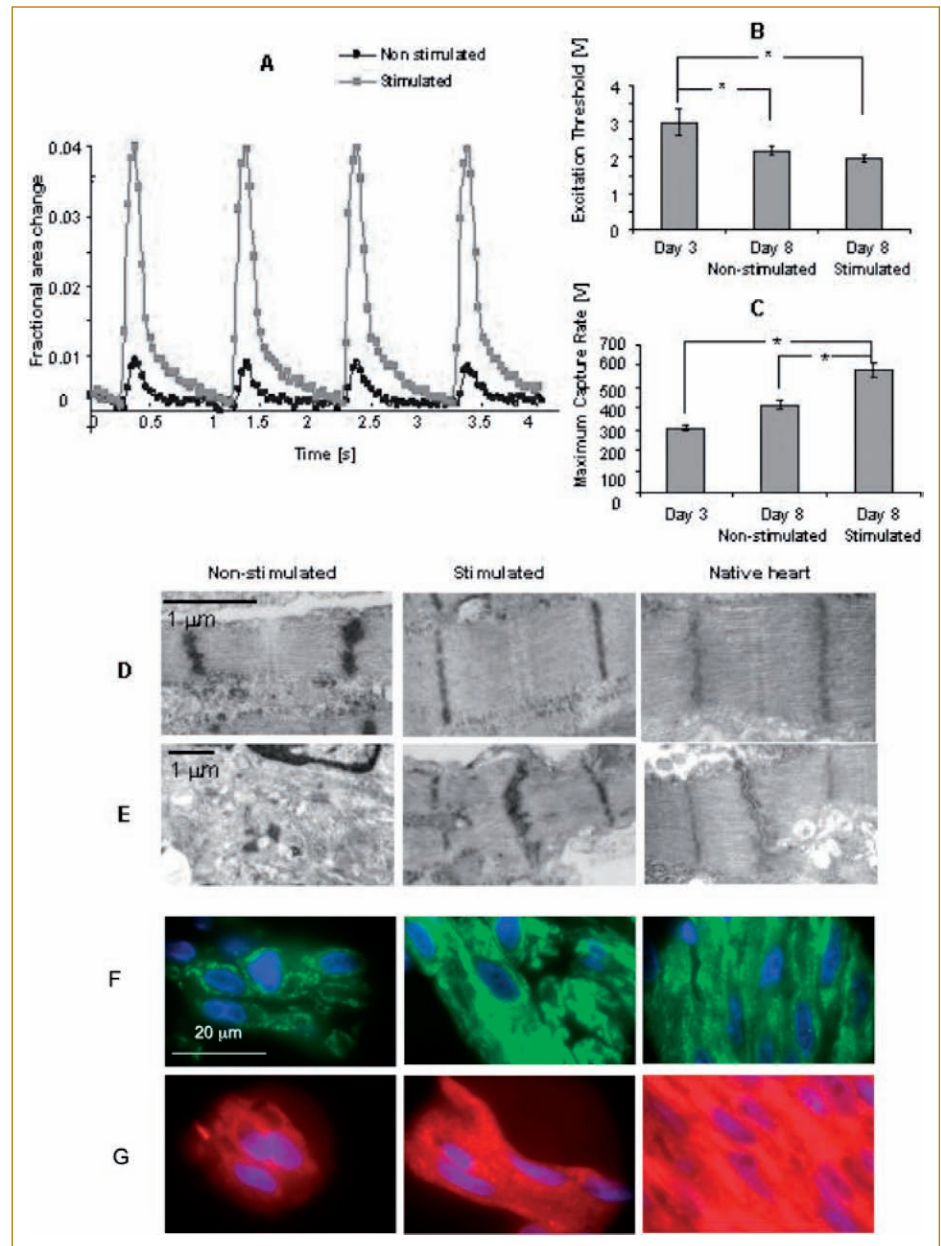

### Excitation–Contraction Coupling: Electrical Stimulation

In native heart, mechanical stretch is induced by electrical signals, and the orderly coupling between electrical pacing signals and macroscopic contractions is crucial for the development and function of native myocardium (Severs, 2000). We therefore hypothesized that applying electrical signals designed to induce synchronous construct contractions would enhance cell differentiation and functional assembly of engineered tissue via physiologically relevant mechanisms. To test this hypothesis, cardiac constructs prepared by seeding collagen sponges ( $6 \times 8 \times 1.5$  mm) with

neonatal rat ventricular cells ( $5 \cdot 10^6$ ) were stimulated using supra-threshold square biphasic pulses (2 ms duration, 1 Hz, 5 V). The stimulation was initiated after one to five days of scaffold seeding (three-day period was optimal) and applied for up to eight days.

The application of electrical stimulation during construct cultivation markedly enhanced the contractile behavior. After eight days of culture, the amplitude of contractions was sevenfold higher in stimulated than in nonstimulated constructs (Fig. 38.5A), a result of the progressive increase with the duration of culture. The excitation threshold (ET, the minimum voltage at which the entire construct was observed to beat) decreased (Fig. 38.5B) and the maximum

capture rate (MCR, the maximum pacing frequency for synchronous construct contractions) increased (Fig. 38.5C) both with time and due to electrical stimulation, suggesting functional coupling of the cells. The shape, amplitude ( $\sim 100$  mV), and duration ( $\sim 200$  ms) of the electrical activity recorded for cells in constructs stimulated during culture were similar to action potentials reported for constructs that were mechanically stimulated during culture (Zimmermann *et al.*, 2002b).

After eight days, stimulated constructs demonstrated a remarkable level of ultrastructural differentiation, comparable in several respects to that of native myocardium. Cells in stimulated constructs were aligned and elongated and contained centrally positioned elongated nuclei, in contrast

to round cells in nonstimulated constructs, which had a high nucleus-to-cytoplasm ratio. Stimulated constructs and neonatal ventricles contained abundant mitochondria positioned between myofibrils, in contrast to nonstimulated constructs, containing mitochondria scattered around the cytoplasm and substantially larger amounts of glycogen. Electrical stimulation induced the development of long, well-aligned registers of sarcomeres that closely resembled those in native myocardium (Fig. 38.5D), representing a hallmark of maturing cardiomyocytes (Severs, 2000). The volume fraction of sarcomeres in stimulated eight-day constructs was indistinguishable from that measured for neonatal ventricles (Olivetti *et al.*, 1980); in contrast, non-stimulated constructs contained only scattered and poorly

organized sarcomeres. In stimulated constructs intercalated discs were positioned between aligned Z lines (Fig. 38.5E) and were as frequent as in neonatal ventricles; gap junctions were also substantially better developed and more frequent.

Myofibers aligned in the direction of the electrical field lines, possibly in an attempt to decrease the apparent ET in response to pacing (Tung *et al.*, 1991). In contrast, cells in nonstimulated constructs stayed round and expressed relatively low levels of cardiac markers. After eight days, stimulated constructs exhibited a markedly higher density of Cx-43 than either early (three-day) or nonstimulated constructs. Notably, the improved contractile properties of electrically stimulated constructs were not reflected in any apparent differences in construct cellularity, cell damage, or cell metabolism, but correlated instead with cell differentiation. Myofibers aligned in the direction of the electrical field lines, possibly in an attempt to decrease the apparent ET in response to pacing (Tung *et al.*, 1991). Stimulated constructs and neonatal ventricles expressed high levels of cardiac Tn-I, sarcomeric  $\alpha$ -actin, Cx-43,  $\alpha$ -MHC, and  $\beta$ -MHC and contained elongated cells aligned in parallel (Fig. 38.5F, G). In contrast, cells in nonstimulated constructs stayed round and expressed relatively low levels of cardiac markers. Cross-striations characteristic of mature cardiac myocytes were detected in stimulated constructs and native ventricles but not in nonstimulated constructs.

In our ongoing studies we performed optical mapping to measure the impulse propagation in the constructs cultivated in the presence or absence of electrical field stimulation. The constructs in the stimulated group had impulse propagation of  $14.4 \pm 2.7$  V/cm, which was significantly higher than the impulse propagation in the nonstimulated group of  $8.6 \pm 3.0$  V/cm. Our feasibility studies of implantation of the stimulated constructs in the rat model of myocardial infarction indicate that the constructs readily integrate with the host tissue and vascularize following implantation.

### Multiple Cell Types

Attempts to engineer cardiac tissue, including our previous studies, typically involve the use of cell populations enriched for cardiomyocytes (CM) by preplating and removing rapidly adhering cells (Bursac *et al.*, 1999; Carrier *et al.*, 1999; Fink *et al.*, 2000; Papadaki *et al.*, 2001; Zimmermann *et al.*, 2002b). Zimmermann *et al.* (2002b) were the first to recognize the importance of the presence of multiple cell types for the *in vitro* cultivation of heart tissue in their system, which involves the application of cyclic stretch. In separate studies, Akhyari *et al.* (2002) detected the presence of newly synthesized collagen network in the tissue constructs based on the passage of three human pediatric heart cells, suggesting that fibroblasts may play a role in the remodeling of engineered cardiac constructs *in vitro*.

We hypothesized that scaffold pretreatment with cardiac fibroblasts prior to the cultivation of cardiac myocytes can enhance functional assembly of the engineered cardiac constructs by creating an environment supportive of cardiomyocyte attachment, differentiation, and contractility. Neonatal rat heart cells were sorted and used to prepare three distinct cell populations: rapidly plating cells, identified as cardiac fibroblasts (CF); slowly plating cells, identified as cardiac myocytes (CM); and the unseparated initial population of cells (US). We investigated the structure and function of engineered constructs with respect to the use of the coculture (as compared to CM alone) and with respect to the regime of coculture (concurrent culture of CM and CF using US population; sequential coculture of CF and CM). Constructs formed with CF alone were used as an additional control. The cells were cultured for 11 days on porous scaffolds made of poly(glycerol sebacate) (PGS).

Constructs in the CF + CM and CM groups exhibited similar fractions of myocytes (~55%) and fibroblasts (~20%) and similar amounts of cardiac-specific proteins. However, the constructs in the CF + CM group had significantly higher contractile amplitude than the CM group ( $p < 0.05$ ) and significantly lower excitation threshold than the US group ( $p < 0.05$ ). Also, the CF + CM group exhibited a stratified, 100- to 200- $\mu$ m-thick tissue-like structure that contained some elongated CM, in contrast to relatively less organized cells in the US and CM groups (Fig. 38.6). Thus, the sequential coculture of CF and CM on a synthetic elastomer scaffold created an environment supportive of cardiomyocyte attachment, differentiation, and contractile function. It is possible that CF played the role of a feeder layer for the cardiac cells and conditioned the scaffold by secreting collagen, which is a natural substrate for CM attachment. We believe that this approach can be used routinely to precondition the scaffolds for cardiac-tissue engineering.

## VI. ENGINEERED HEART TISSUE BY MECHANICAL STIMULATION OF CELLS IN COLLAGEN GELS

A significant approach to cardiac-tissue engineering, established by Eschenhagen and colleagues (Eschenhagen *et al.*, 1997; Fink *et al.*, 2000; Zimmermann *et al.*, 2000, 2002b), involves the cultivation of neonatal rat heart cells in collagen gel and Matrigel, in the presence of growth factors. This approach is also biomimetic in nature, because it involves the utilization of mechanical stretch as a physiologically relevant signal for cell differentiation. The cultured tissues are subjected to sustained mechanical strain. Under these conditions, cardiomyocytes and nonmyocytes form 3D cardiac organoids (Bursac *et al.*, 1999; Carrier *et al.*, 1999; Papadaki *et al.*, 2001), a well-organized and highly differentiated cardiac muscle syncytium, that exhibited the contractile and electrophysiological properties of working myocardium. The first implantation experi-

**FIG. 38.6.** Differential effects of cardiac cell subpopulations on construct appearance, fibroblast markers, and myocyte markers. Top row: vimentin/actin co-actin for fibroblasts (red) and myocytes (green). Middle row: cardiac myocytes are stained green for Tn-1. Bottom row: prolyl-4-hydroxylase, involved in collagen synthesis by fibroblasts stained green; nuclei are shown in blue (DAPI).

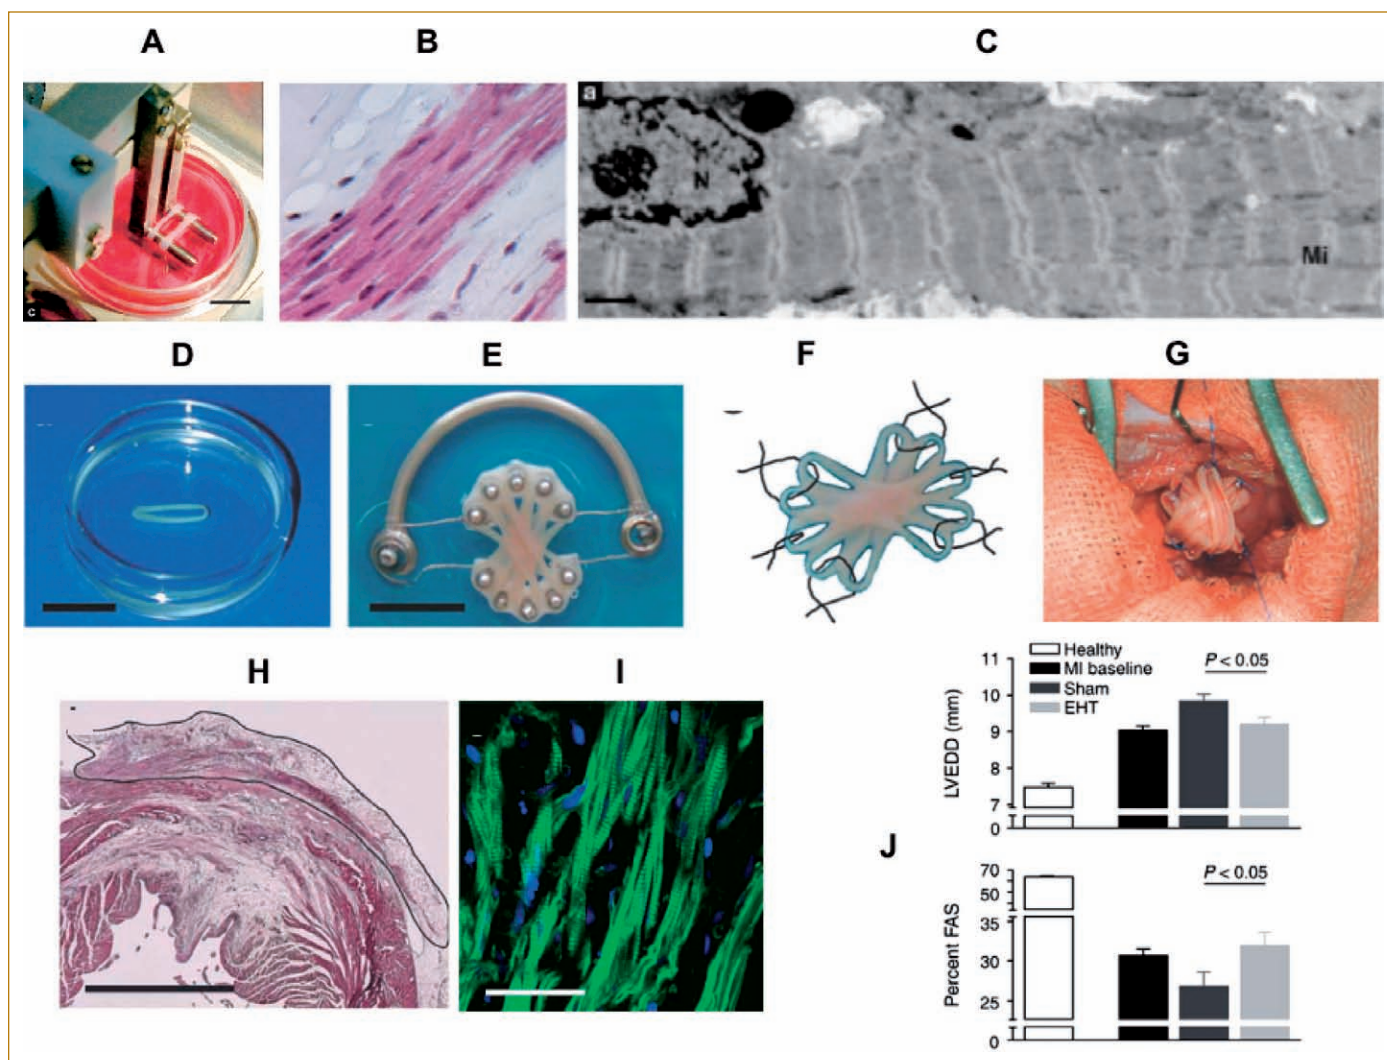

ments in healthy rats showed survival, strong vascularization, and signs of terminal differentiation of cardiac tissue grafts (Zimmermann *et al.*, 2002a). More recent work demonstrates rigorously, and using multiple molecular, structural, and functional assays, that these constructs can be engineered in forms suitable for implantation on infarcted rat hearts and that they delay the thinning of the heart wall and induce functional improvement (Zimmermann *et al.*, 2006).

In an early setup, neonatal rat ventricular myocytes were resuspended in a gel consisting of collagen I diluted in DMEM and Matrigel (Fink *et al.*, 2000). For each piece of tissue, 0.7 mL of the cell/gel mix was poured into a well (11 × 17 × 4 mm) made of silicone rubber containing one set of Velcro-coated silicone tubes (7-mm length, 3-mm OD, 2-mm ID). One tissue culture dish could hold six wells. The mixture was allowed to gel at 37°C for 60 min before culture medium was added. After four days in culture, a strip of biconcave tissue was formed, fixed at each side to a piece of

silicone tubing. The tissues were transferred to a custom-made motorized stretching device that consisted of a spring attached between two stretching bars, one fixed, the other moving, with holders that attach to the pieces of silicone tubing at each end of the engineered cardiac tissue. A unidirectional and cyclic stretch at a frequency of 1.5 Hz and a strain rate of up to 20% was employed for six days. Stretched constructs exhibited an improved organization of cardiac myocytes into parallel arrays of rod-shaped cells. They had increased cell length and width and higher mitochondrial density and contained longer myofilaments. Compared with the unstretched controls, RNA/DNA increased by 100% and the protein/cell ratio increased by 50%. The force of contraction was higher in stretched constructs under basal conditions and after stimulation with isoprenaline (Fink *et al.*, 2000).

In an improved setup, neonatal rat cardiac cells were resuspended in the collagen/Matrigel mix and cast into circular molds (Zimmermann *et al.*, 2006). After seven days in

**FIG. 38.7.** Engineered heart tissue by mechanical stimulation. (A) Eschenhagen and Zimmermann designed a bioreactor that provides cyclic mechanical stretch to engineered heart tissue based on neonatal rat cardiomyocytes and collagen gel. Mechanical stimulation yielded elongated cardiomyocytes (B) with a remarkably well-developed contractile apparatus (C) (With permission from Zimmermann *et al.*, 2002b). (D)–(F) (With permission from Zimmermann *et al.*, 2006) A complex star-shaped engineered heart tissue was formed by stacking five ring-shaped constructs engineered using neonatal rat heart cells, collagen gel, and the bioreactor shown in A. The resulting synchronously contracting multiloop construct (E) was sutured (F) on top of an infarct scar caused by LAD ligation (G). The patch integrated well with the host myocardium (H). Implanted cells formed elongated myofibers with a well-developed contractile apparatus (I, green: actin; blue: nuclei). (J) Four weeks following implantation, left ventricular end-diastolic diameter (LVEDD, top graph) and fractional area shortening (FAS, bottom graph) measured by echocardiography showed that engineered heart tissue prevented further dilation and improved fractional area shortening of infarcted hearts as compared to controls. “Healthy” indicates untreated controls, “MI baseline” indicates values measured two weeks after myocardial infarction, “Sham” indicates four-week data for sham-operated rats, and “EHT” indicates four-week data for rats that received engineered constructs. Scale bars: A: 10 mm; B: 30  $\mu$ m; C: 1  $\mu$ m; D, E: 10 mm; H: 5 mm; I: 5  $\mu$ m. Reproduced with permission from Zimmermann *et al.*, 2006.

culture, the strips of cardiac tissue were placed around two rods, each fixed to a stretching bar of a custom-made mechanical stretcher and subjected to unidirectional and cyclic stretch at a 10% strain rate and 2 Hz (Fig. 38.7A). The histology and immunohistochemistry revealed the formation of intensively interconnected, longitudinally oriented cardiac muscle bundles with morphological features resembling adult rather than immature native tissue (Fig. 38.7B). Fibroblasts and macrophages were found scattered through

the construct, and, at the high magnification, capillary structures positive for CD31 were noted. Cardiomyocytes exhibited well-developed ultrastructural features: sarcomeres arranged in myofibrils, with well-developed Z, I, A, H, and M bands, specialized cell–cell junctions (gap and adherence junctions), T tubules as well as well-developed basement membrane. The constructs exhibited contractile properties similar to those of the native tissue, with a high ratio of twitch to resting tension, a strong  $\beta$ -adrenergic

response, and action potentials characteristic of rat ventricular myocytes.

Zimmerman *et al.* (2002a) placed cardiac-tissue rings cultivated in the presence of mechanical stimulation onto uninjured hearts of Fisher 344 rats for 14 days. They noticed that although both cells and collagen were isolated from Fisher rats, immunosuppression was required for maintenance of heart tissue upon implantation. In the absence of immunosuppression, even in the syngeneic approach, cardiac constructs completely degraded after only two weeks *in vivo*. It is unknown what exactly caused the response; it is possible that it was the remainder of serum or chick extract. Regardless, the finding has implications for the potential implantation of cardiac patches in clinical settings.

In recent studies (Zimmermann, 2006), the same group created large, 1- to 4-mm-thick tissue constructs from neonatal rat heart cells and demonstrated the capability of these constructs to support contractile function of infarcted hearts in a immunosuppressed rat model. Four weeks following implantation, engineered heart-tissue grafts showed electrical coupling to the native myocardium. As compared to controls (untreated infarctions, sham operated rats, non-contractile constructs), engineered heart tissue prevented further dilation of the ventricle wall and improved fractional area shortening of infarcted hearts. Four weeks after grafting, engineered tissues had a high connective-tissue content and contained ~400- $\mu$ m-thick strands of compact and well-differentiated cardiacklike muscles. The graft was electrically coupled to the host myocardium, as indicated by undelayed impulse propagation. The maximum conduction velocity in implanted grafts ( $0.55 \pm 0.16$  m/s longitudinally,  $0.16 \pm 0.07$  m/s transversally) was comparable to the conduction velocity in noninfarcted myocardium ( $0.69 \pm 0.06$  m/s and  $0.19 \pm 0.05$  m/s, respectively). Anisotropy, determined from the ratio of the longitudinal and transversal conduction velocities, in the grafts was similar to that in noninfarcted myocardium ( $4.15 \pm 0.8$  versus  $4.07 \pm 0.91$ ).

## VII. CELL-SHEET TISSUE ENGINEERING

Shimizu *et al.* (2002) created sheets of neonatal rat cardiomyocytes by plating isolated cells onto a temperature-sensitive poly(*N*-isopropylacrylamide) surface. The change in temperature from 37°C to 32°C causes the cell monolayer to detach. The initial surface area decreases during the detachment approximately fivefold, and the thickness of the cell sheet increases from approximately 20  $\mu$ m to approximately 45  $\mu$ m (Fig. 38.8A). When the cell sheets were layered over each other, the electrical communication was established, as evidenced by electrical signals measured by electrodes (Fig. 38.8B), and spontaneous beating was observed macroscopically. When implanted subcutaneously in nude rats, cell sheets survived for up to 12 weeks and vascularized. The outcomes were substantially better for implantation in three-week as compared to eight-week rats (Fig. 38.8C).

In separate recent studies (Furuta *et al.*, 2006), layered cell sheets formed using the neonatal rat cardiomyocytes and reinforced using an additional layer of collagen were studied in a nude rat model of myocardial infarction. The cell sheets were implanted immediately following ligation, and the outcomes were evaluated at one week and four weeks following implantation. Electrophysiological studies demonstrated functional integration of the grafted tissue and the propagation of APs without observable arrhythmias. The functional improvement was indicated by several measured parameters, including the AP amplitude, which was well maintained in the grafted group but not in untreated controls (Fig. 38.8D).

In another recent study, this method was extended to the formation of cell sheets using adipose-derived rat mesenchymal stem cells (MSC). The cell sheets were tested in a rat model of myocardial infarction. Four weeks following ligation, the cell sheets were implanted, and they were evaluated after an additional four weeks. The grafts formed a layer that contained some new blood vessels, viable undifferentiated cells, and a few cardiomyocytes (Fig. 38.8E). Notably, the implantation of cell sheets made using MSC reversed wall thinning in the scar area, in contrast to the control cell sheets made using dermal fibroblasts, which had no effect (Fig. 38.8F).

Overall, the method provides thin sheets of cells that express cardiac features *in vitro* and have the capability for cardiac repair *in vivo*. The studies involving rat MSC also represent an important step toward establishing clinically relevant cell sources.

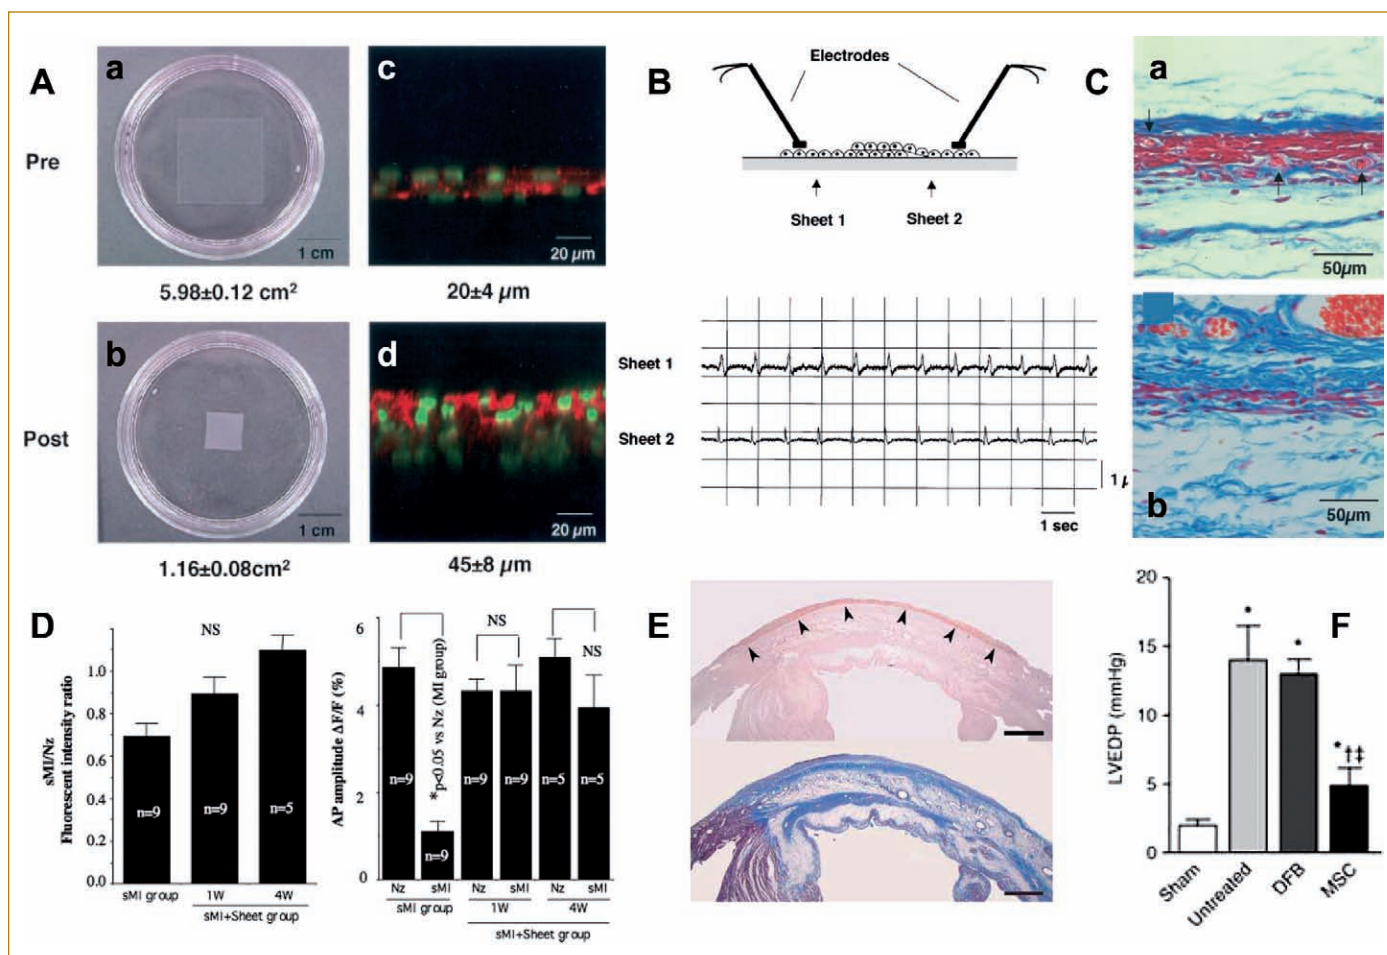

## VIII. SUMMARY AND CURRENT RESEARCH NEEDS

### Summary

The overall goal of cardiac-tissue engineering is to direct the cells to establish the physiological structure and function of the heart tissue across different hierarchical scales. We described three significant and representative approaches to cardiac-tissue engineering that regulate cell differentiation and functional assembly of neonatal rat heart cells (the best-established cell model) by employing some of the signals that drive the development and function of normal heart. The differences in the conditions used to create cardiac tissues and the measured tissue outcomes between these approaches are instructive for the understanding of the state of the art of the field of cardiac-tissue engineering.

### Approaches to Cardiac-Tissue Engineering

The biomimetic approach involves an integrated use of cells, biomaterial scaffolds, and bioreactors to engineer compact, millimeters thick, synchronously contracting cardiac-tissue constructs. The system design is based on providing (1) convective-diffusive oxygen transport (critical

**FIG. 38.8.** Cell-sheet engineering. **(A)** Neonatal rat cardiomyocytes were cultured on thermoresponsive polymer surfaces for four days, and the formed cell sheets were detached by lowering the temperature from 37°C to 32°C. Cell sheets before **(a)** and after **(b)** detachment. The numbers refer to the surface area of the cell sheet. The respective sheet cross sections and thicknesses are shown on the right. Scale bar: 20 μm. **(B)** Two layered cardiomyocyte sheets established electrical communication, as evidenced by measured electrical potentials. **(C)** Histological analysis of cell sheets implanted subcutaneously in **(a)** three-week-old rats and **(b)** eight-week-old rats. Significant differences in tissue morphology were observed as a function of the age of the recipient. Scale bar: 50 μm. **(D)** Neonatal rat cardiomyocyte sheets described in images A–C were stabilized by a collagen layer and implanted, in separate studies, onto infarcted rat hearts immediately after injury. Action potentials (APs) were measured at explanted hearts one and four weeks following implantation, using an optical fluorescence–based method. The graph on the left shows the fluorescent intensity of the untreated (sMI) group and the treated (sMI + sheet) group. The graph on the right shows the preservation of the AP amplitude in the treated group and the loss of the AP in the sMI group. **(E)** Extent of monolayered MSCs 48 h after transplantation (arrows). Scale bar: 100 μm. **(F)** Left ventricle end-diastolic pressure (LVEDP), measured by catheterization eight weeks after coronary ligation (four weeks after transplantation) in four groups of rats (sham; untreated; treated with a cell sheet made using dermal fibroblasts, DFB; treated with a cell sheet made of rat adipose-derived mesenchymal stem cells). A, B, and C reproduced with permission from Shimizu *et al.* (2002); panels from Fig. 1, Fig. 2, and Fig. 3B, C; D was reproduced with permission from Furuta *et al.* (2006), Fig. 5C, D; E and F reproduced with permission from Miyahara *et al.* (2006), Fig. 2c and Fig. 5a.

for cell survival and function) and (2) excitation–contraction coupling (critical for cell differentiation and assembly). To mimic the capillary network, culture medium is perfused through a channeled scaffold seeded with cells at a physiologic density; to mimic the oxygen supply from hemoglobin, the culture medium is supplemented with an oxygen carrier (PFC emulsion). To promote cell differentiation and functional assembly, cultured constructs were subjected to electrical signals designed to mimic those in native heart and to

induce synchronous construct contractions. Perfusion of culture medium containing PFC enabled the maintenance of a physiologic density of viable, differentiated cells in millimeters-thick constructs. Electrical field stimulation induced cell alignment and coupling, increased the amplitude of synchronous contractions, and resulted in a remarkable level of ultrastructural organization of engineered myocardium, over only eight days of cultivation (Radisic *et al.*, 2004b).

Eschenhagen and Zimmermann demonstrated that mechanical stimulation in a physiological regime yields functional and highly differentiated cardiac muscle, which was successfully utilized to improve contractile function of infarcted myocardium. Their approach has recently been validated by demonstration that it can be utilized to engineer cardiac tissue based on embryonic stem cell–derived cardiomyocytes (Guo *et al.*, 2006).

The cell-sheet approach pioneered by Okano and colleagues sets a novel paradigm for cardiac-tissue engineering that eliminated the need for a scaffold or a hydrogel for assembly of functional cardiac tissue. The method, based on layering confluent cell monolayers, has been validated by extensive *in vivo* and electrophysiological studies. This technique can render itself highly useful in co- and triculture studies.

### Challenge 1: Human Cell Source

One major challenge for cardiac-tissue engineering and its application in regenerative medicine is to extend the principles described earlier to the cultivation of functional cardiac grafts based on human cells. Practically all tissue-engineering work has been done using neonatal rat heart cells. Several different human cell sources are currently under consideration. Adult cardiac myocytes are not suitable because they are terminally differentiated and have no ability to proliferate (Soonpaa and Field, 1998). Transplantation of cell sheets based on adipose tissue–derived stem cells improved contractile function in a rat model of coronary artery ligation (Miyahara *et al.*, 2006). Emerging recent work suggests that the heart may contain resident progenitor cells. However, it appears that there is more than one heart cell subpopulation that fits the description of a cardiac progenitor. It remains to be determined if the progenitors, regardless of their marker, can be isolated from adult human biopsies and propagated to numbers sufficient to engineer a cardiac patch ( $>10^8$  cells/patient). Also, for each of the candidate cell sources, the exact factors that need to be applied *in vitro* to induce and support cardiac cell differentiation and subsequent tissue development remain to be identified and optimized.

### Challenge 2: Improved Tissue-Engineering Systems

The second challenge is the need to advance the capabilities of our culture systems. Our most advanced existing bioreactors can provide *either* local microenvironmental control of oxygen and pH (via medium perfusion) *or* the application of physical stimuli (via electrical stimulation). A system providing *both factors simultaneously* was recently

developed in our laboratory to further our biomimetic methods of cardiac-tissue engineering, by subjecting the cultured cells to *multiple signals* present in the native heart. The combined application of the oxygen supply and electrical stimulation designed to mimic those *in vivo* is expected to accelerate cell differentiation and functional assembly. This system could also enable controlled studies of cardiac development and function.

### Challenge 3: Vascularization

The third major challenge is the need for vascularization. In spite of many meritorious efforts in recent years (Ennett and Mooney, 2002; Jain, 2003; Levenberg *et al.*, 2005), vascularization of engineered tissues remains a fundamental and all-encompassing problem. Not surprisingly, tissue engineering has been most successful with tissues that either are thin (e.g., bladder) or have low oxygen requirements (e.g., cartilage). Our current inability to vascularize and perfuse thick cell masses has hindered efforts to build clinically useful tissues and, most critically, cardiac grafts. Vascular supply has multiple roles: (1) exchange of nutrients (most critically oxygen), metabolites, and regulatory factors between the cells and the environment; (2) paracrine signaling between the endothelial and cardiac cells; and (3) separation of the tissue phase with cardiac myocytes from the blood flow, and shielding of cardiomyocytes from hydrodynamic shear. Clearly, perfusion alone does not suffice, and the provision of the functions for the long term likely requires the formation of a stable and mature vascular network, functionally integrated with the macroscopic flow.

### Challenge 4: Interactions Between the Fields, Translational Research

The fourth and rather general challenge is for more effective interdisciplinary and translational research. The growing interactions between the fields of tissue engineering and developmental biology are expected to facilitate translation of biological principles into our engineering designs. The interactions between tissue engineers and clinicians are expected to help define the requirements, constraints, testing methods, and success criteria for translation into clinical practice. We thus need to continue to move the science and practice of tissue engineering from observational to mechanistic. It is the rational and interdisciplinary approach to tissue engineering that can bring us closer to producing biological grafts that can reestablish normal tissue structure and function across different-size scales, in the long term, and with the ability to remodel in response to environmental factors, growth, and aging.

## IX. ACKNOWLEDGMENTS

The cardiac-tissue-engineering work in our laboratories has been supported by the National Institutes of Health (NHLBI,

NIBIB), the National Aeronautics and Space Administration, and the Juvenile Diabetes Research Foundation.

### I. INTRODUCTION

Principles of tissue engineering are now being applied in the induction and development of microvascular networks as well as capacitance conduits, including the *in vitro* and *in vivo* biologic modification of synthetic vascular grafts and the generation of tissue-engineered blood vessels in bioreactors and *in vivo*. Yet 100 years since the development of vascular anastomoses, small-diameter vascular grafts continue to encounter significant translational barriers to widespread clinical application. This is probably because much of the reported progress in the field has been simplistic in design. Still these studies have led to a more complex and realistic understanding of the physiologic and pathologic processes occurring in a coordinated fashion both prior to and after implantation into the circulation. This understanding has allowed old ideas to become new again and may well provide the bridge necessary to cross this 100-year chasm that has separated patients from the ideal blood vessel substitute.

Alexis Carrel, the father of vascular surgery, was the first to describe the utility and shortfalls of autogenous and synthetic grafts. The main limitation discussed was the lack of durability for small-diameter synthetic grafts. For this reason he partnered with Charles Lindbergh to create new blood vessels *de novo* as a substitute for autogenous vessels, thus beginning the field of cardiovascular tissue engineering (Fig. 39.1). The first clinical successes of synthetic vascular grafts

were subsequently delayed until the 1950s, when Voorhees developed the first fabric graft, termed the Vinyon N vascular prosthesis (Voorhees *et al.*, 1952); several ethylene-based synthetic grafts followed. Again, large-vessel grafts demonstrated excellent results, but small-diameter grafts did not. Now, more than 50 years after Voorhees and 100 years since the landmark discoveries of Carrel, small-diameter grafting continues to be associated with poor long-term patency rates as compared to autogenous vessels.

Unfortunately, cardiovascular disease has become more prevalent in the last 100 years, now being the leading cause of death in the world and the second leading cause of death for all Americans. Despite improvements in the medical therapy of cardiovascular disease, the number of vascular interventions (combining bypass grafting and angioplasty  $\pm$  stenting) has increased in recent years. Currently there are more than 1.4 million bypass operations annually in the United States, and, although autogenous veins or arteries provide the best patency rates for cardiovascular bypass, many patients do not have suitable autogenous vessels available for use. For these reasons the creation of durable small-vessel vascular conduits is critical to the successful treatment of cardiovascular disease and injury.

Since the idea of a nonreactive vascular conduit as an ideal graft is no longer accepted, current initiatives emphasize its incorporation into the surrounding vessels and tissue. Such approaches include the development of non-

**FIG. 39.1.** “The culture of organs.” Illustration of the classic 1938 text coauthored by Alexis Carrel and Charles Lindbergh outlining the potential uses of tissue engineering.

autologous biologics, synthetic grafts that promote or support tissue ingrowth, and tissue-engineered vascular grafts that mimic the functional properties of the blood vessel.

This chapter discusses the current status of vascular bypass grafts, the modifications of these grafts designed to facilitate healing, arteriogenesis, and therapeutic angiogenesis, and tissue-engineered vascular grafts. It concludes with tissue-engineering approaches to the rapidly advancing field of endovascular therapeutics.

## II. CURRENT STATUS OF VASCULAR CONDUITS

### Conduit Patency and Failure

Large-diameter grafts, such as those used for aortic reconstruction, have a superb five-year patency rate, approaching 95%. When synthetic grafts are used in the infrapopliteal region, the results are worse: One- and three-year patency rates for infrapopliteal bypass using ePTFE grafts was 43% and 30%, respectively (Veith *et al.*, 1986), and the

outcomes are even more dire for those with comorbidities such as diabetes and renal insufficiency.

For smaller arteries the results with autogenous vein are also less than impressive, with the exception being the left internal mammary artery for coronary artery bypass grafting, which has a greater than 90% five-year patency. Currently, autogenous vein is the conduit of choice for concomitant coronary artery bypass grafting and infrainguinal vascular reconstruction. However, its primary and secondary patency rates at one year in a patient population with critical limb ischemia were recently reported to be 61% and 80%, respectively (Conte *et al.*, 2006); the results were not better in the coronary vasculature. These results are strikingly similar to those reported over 30 years ago.

A variety of mechanisms can lead to vascular graft occlusion and occur in a defined temporal sequence. Immediate graft failure is usually the result of technical error from the operation or from the patient's having a hypercoagulable status. Failure in the first month following graft placement is most likely the result of thrombosis secondary to distal flow resistance. Small-diameter grafts are prone to early thrombosis because of their lower flow rates and the higher resistance in their outflow vessels. Thus graft thrombogenicity is of primary concern early after graft placement.

Anastomotic pseudointimal hyperplasia<sup>1</sup> is the most common reason for graft failure from six months to three years after graft insertion, and later graft failure is frequently due to the progression of distal atherosclerotic disease. Small-diameter grafts are particularly susceptible to anastomotic myointimal hyperplasia (IH). Analogously, other vascular interventions, such as angioplasty and endarterectomy, fail because there is a limited regenerative endothelial cell (EC) capacity after injury in humans, leading directly to both the thrombotic and myointimal hyperplastic complications.

Pathophysiologically, denuded intima or an exposed luminal area of a graft may lead to thrombosis via platelet deposition and activation of the coagulation cascade, and over time it promotes pathologic smooth muscle cell (SMC) migration, proliferation, and extracellular matrix (ECM) deposition, leading to IH. IH in turn narrows the vessel lumen (restenosis), decreasing blood flow to the point where it may promote local thrombosis or lead to symptomatic ischemia in the relevant distal-end organs, such as the brain (cardiovascular accidents), heart (myocardial infarctions), and extremities (critical limb ischemia). Since thrombogenicity and intimal hyperplasia represent the most common causes of graft failure and both are mediated at the luminal interface of the vessel or graft, the inner lining of grafts has

<sup>1</sup> Although the terms *myointimal*, *neointimal*, and *pseudointimal hyperplasia* are often used interchangeably, here *neointima* is used to describe areas that include all normal intimal constituents, including ECs, whereas *pseudointima* is used to describe the relatively acellular tissue within clinically implanted vascular grafts; *myointima* is used more generically to include both types.

been the subject of much investigation. To date, however, we are still in the early stages of understanding and treating the complications of vascular interventions.

## Cellular and Molecular Mediators of Graft Outcome

### Normal and Pathologic Composition of the Vessel Wall

For arteries, the intima (*tunica intima*) is composed of a relatively quiescent EC monolayer and its surrounding basement membrane proteins (e.g., type IV collagen, perlecan). Together with the underlying internal elastic lamina, the intima maintains SMCs in their contractile state and inhibits pathologic SMC activity. Deep to the intima and separated by the internal elastic lamina is the medial layer (*tunica media*). It is the thickest arterial layer and in non-pathologic states is composed of SMCs and many ECM proteins (e.g., elastin and the fibrillar collagens, such as type I collagen). Medial SMCs here respond to intimal cues to dilate or contract the vessel. The medial layer in veins is difficult to define because it lacks the internal elastic lamina, but after exposure to arterial flow via vein graft bypass, they develop a defined media over time that has similarities to that of native artery. The external elastic lamina defines the abluminal edge of the media, and the vaso vasorum, which supplies most of the vessel wall's (outer two-thirds) metabolic needs, is prominent in the outer adventitial vessel layer (*tunica adventitia*). The adventitia is composed of loosely arranged connective tissue and fibroblasts, and it may play an important role in the progression of restenosis and late interventional failure after angioplasty due to vessel remodeling, since adventitial delivery of therapeutic treatments has reduced these complications (Scott *et al.*, 1996).

In the absence of disease or injury, native blood vessels possess an endothelial lining that constantly secretes bioactive substances inhibiting thrombosis, promoting fibrinolysis, and inhibiting SMCs from switching from a contractile to a synthetic phenotype. All the while the intima directly or indirectly (through cues to the vessel media) is maintaining blood flow to meet distal tissue demands. Thus, reestablishing this type of intimal lining quickly and completely in vascular grafts is vital to the normal function of small-diameter vascular grafts. Unfortunately, and unlike most animal models in use, which spontaneously endothelialize synthetic grafts, humans manifest only limited endothelial cell ingrowth, not extending beyond 1–2 cm of both anastomoses. However, endothelial islands have been described in the midportions of grafts at significant distances from the anastomosis, suggesting that other EC sources for graft endothelialization may exist. Interstitial tissue ingrowth accompanied by microvessels from the perigraft tissue is one potential source. There is also evidence that circulating endothelial cells, endothelial progenitor cells (EPC), or stem cells can be directed to these areas. Such homing can be promoted through affixation of EC-attractant antibodies to

the grafts in a similar fashion as has been utilized in coronary artery stents (Aoki *et al.*, 2005).

However, ECs growing on prosthetic graft surfaces are not necessarily the same as their normal quiescent counterparts in uninjured vessels. These ECs are often activated, secreting bioactive substances (PDGF) that actually promote thrombogenesis and changes in SMC phenotype. This has been seen in the perianastomotic region, which is the most frequent site of interventional failure after operation. SMCs found within the myointima of prosthetic grafts are also functionally altered. They produce significantly higher amounts of PDGF, as well as various extracellular matrix proteins, than those of the adjacent vessel, which, along with the body's inflammatory reaction to prosthetic material, contribute to the development of intimal hyperplasia (Pitsch *et al.*, 1997).

### Inflammation

The inflammatory response to vascular interventions is complex. It is mediated by both inflammatory cells and proteins in a cooperative manner. Potent chemoattractants like complement 5a (C5a) and leukotriene B<sub>4</sub> recruit neutrophils to the graft surface, where they localize in the fibrin coagulum of the graft's inner and outer capsule via  $\beta$ 2 integrins. Also, IgG binds to the neutrophils' Fc $\gamma$  receptors, activating the neutrophils' pro-inflammatory response while inhibiting normal clearance of bacteria. Neutrophils also interact with various other deposited proteins, including C3bi and factor X, and they adhere to the endothelial cells in the perianastomotic region through selectin- and integrin-mediated mechanisms. L-Selectin is thought to modulate neutrophil/endothelial cell interactions by presenting neutrophil ligands to both the E- and P-selectins on the vascular endothelium. In addition selectin-carbohydrate bonds are important for the initial cellular contact, while the integrin-peptide bonds are responsible for strengthening of this adhesion as well as the transmigration of neutrophils. Both intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) on the EC surface bind these integrins as well, and ECs up-regulate ICAM-1 and express VCAM-1 when stimulated by inflammatory agonists like IL-1, TNF, lipopolysaccharide, and thrombin. Further, activated neutrophils release oxygen-free radicals and various proteases, which result in matrix degradation and may inhibit both endothelialization and tissue incorporation of the vascular graft.

Circulating monocytes/macrophages are also attracted to areas of injured or regenerating endothelium, especially in response to IL-1 and TNF. There are many plasma monocyte-recruitment and -activating factors, including LTB<sub>4</sub>, platelet factor 4, and PDGF. This process is propagated in the presence of these plasma-activating factors, driving monocytes to differentiate into macrophages that direct the host's chronic inflammatory response via the release of proteases and oxygen-free radicals.

A variety of cytokines are released from inflammatory cells activated by vascular grafts. Lactide/glycolide grafts are composed of bioresorbable materials that are phagocytosed by macrophages; in culture these materials stimulate macrophages to release mitogens that stimulate vascular cells. This mitogenic activity appears to be related to the secretion of FGF-2, since pretreatment of the culture media with a neutralizing anti-FGF-2 antibody significantly diminishes the stimulatory effect on smooth muscle cell growth (Greisler *et al.*, 1991). Cultured monocytes and macrophages incubated with Dacron and ePTFE have been demonstrated to produce different amounts of IL-1 $\beta$ , IL-6, and TNF- $\alpha$  that are biomaterial specific (Swartbol *et al.*, 1997). TNF- $\alpha$  is one of the factors that may contribute to the enhanced proliferation of SMCs caused by leukocyte–biomaterial interactions, while IL-1 may be partly responsible for the increased SMC proliferation caused by leukocyte–EC reaction. IL-1 also induces up-regulation of IGF-1 expression in ECs, and coculture of neutrophils with IL-1 $\beta$ -treated ECs dramatically increases PDGF release.

Since the inflammatory reaction elicits a cascade of growth processes, it has been proposed that approaches attenuating the initial inflammatory reaction may improve long-term graft patency. Alternatively, directing the inflammatory response to promote favorable cellular and protein responses may promote intimal generation and tissue incorporation.

### III. PHYSICAL OR CHEMICAL MODIFICATION OF CURRENT GRAFTS TO IMPROVE DURABILITY

The long-term patency of vascular grafts depends on the intrinsic properties of the graft itself and the hemodynamic environment in which the graft is placed, as well as patient variables (e.g., diabetes and renal failure) and may or may not be improved by prior or concomitant interventions such as proximal or distal angioplasty. Since it is now clear that tissue incorporation is important for graft function, grafts that have this ability are now desirable for medium- and small-caliber vessel replacement. Polyethylene terephthalate (Dacron) and expanded polytetrafluoroethylene (ePTFE) are the predominant materials currently used in prosthetic vascular grafts, but both Dacron and ePTFE react with blood components and perigraft tissues in concomitantly beneficial and detrimental fashions. All grafts, regardless of their composition and structure, evoke complex but predictable host responses that begin immediately upon restoration of perfusion, and this improved understanding of the cellular and molecular components of biomaterial/tissue interactions has led to more intelligent designs of grafts that maximize beneficial ingrowth while minimizing the chronic inflammatory changes that lead to graft dilation or occlusion. These approaches include protein adsorptive grafts (growth factors, anticoagulants, antibiot-

ics, etc.) as well as improved graft skeletal construction via synthetic polymers or biologically derived structural proteins that can be bonded to various bioactive cytokines and growth factors to induce a favorable host response.

The humoral and cellular responses to synthetic materials include the deposition of plasma proteins and platelets; infiltration of neutrophils, macrophages, and circulating progenitor cells; and the migration and proliferation of adjacent vascular endothelial and smooth muscle cells. Together these complex interactions mediate the healing response at the graft/blood interface that is critical to future graft durability and patency. Thus, the chemical composition, construction parameters, and biomechanical characteristics of a vascular graft are the predominant mediators of host interaction and largely determine graft fate.

#### Surface Characteristics

The thrombotic interaction at the graft's luminal interface is dependent on both the chemical and physical properties of the graft (e.g., surface charge, surface energy, and roughness). A negative surface charge attenuates platelet adhesion and a positive charge promotes it, while a heterogeneous charge density distribution is also thought to be thrombogenic. Myriad approaches have been designed to limit the thrombotic reaction, including modification of surface properties, incorporation of antiplatelet or anticoagulant substances onto the graft surface, and endothelialization of the luminal surface. In addition to thrombogenic reactions to the luminal surfaces, the rate and extent of endothelialization will vary, depending on the characteristics of the surface (Miller *et al.*, 2004). Therefore properties must be optimized for both reduced thrombogenic reaction and maximized endothelialization.

#### Surface Modifications

The simplest modification of a graft surface is to coat it with an inert polymer. Carbon coating has been known since the 1960s to decrease surface thrombogenicity through its negative charge and hydrophobic nature. Experimentally, the carbon-impregnated prosthetic graft was found experimentally to reduce platelet deposition, but the advantage of these grafts was not confirmed in a prospective multicenter clinical study of 81 carbon-impregnated ePTFE and 79 standard ePTFE grafts for below-knee popliteal and distal bypass. Here the investigators failed to show a significant difference in patency rate between the two groups at up to 12 months after implantation (Bacourt, 1997).

Silicone polymer coating is another approach to altering the luminal surfaces of grafts; this process produces a smooth surface that is devoid of the usual ePTFE graft permeability and texture, and, when followed by plasma glow discharge polymerization, it effectively abolishes pannus tissue ingrowth as well as graft surface neointimal hyperplasia in a baboon arterial interposition graft model. Further, Nojiri *et al.* (1995) have developed a three-layered

graft consisting of Dacron for the outer layer (to promote perigraft tissue incorporation), nonporous polyurethane in the middle layer (to obtain a smooth surface), and a 2-hydroxyethyl methacrylate and styrene (HEMA-st) copolymer coating for the inner layer (to establish a nonthrombogenic blood interface). These grafts with an ID of 3 mm were implanted in canine carotid arteries and remained patent for over one year. Only a monolayer of adsorbed proteins was described on the luminal surface of the grafts, with no pannus ingrowth from the adjacent artery, no thrombus, and no endothelial lining or neointimal formation.

### Protein Adsorption

Another approach is to cover vascular grafts' lumens with proteins. Protein coating has been used as an alternative to preclotting with blood to decrease the initial porosity of Dacron grafts in order to limit transmural blood loss. Knitted Dacron prostheses coated with albumin, gelatin, and collagen have all been available for clinical use. As the impregnated proteins are degraded, the graft undergoes tissue ingrowth.

The albumin coating created in the 1970s was found in animal models to diminish platelet and leukocyte adhesion. In the canine thoracoabdominal aortic model, knitted Dacron grafts impregnated with carbodiimide cross-linked human albumin were compared to identical Dacron grafts with the recipients' blood preclotting. Albumin-impregnated grafts displayed less transinterstitial blood loss at implantation and significantly thinner pseudointimas at 20 weeks (Kang *et al.*, 1997).

Collagen coating establishes a good matrix for cell ingrowth and induces the necessary myointimal formation, and, although native collagen is intrinsically thrombogenic, cross-linking of collagen limits this effect. Promising early results were reported with collagen coating, but a clinical study reported that there was no appreciable difference in graft patency between woven and collagen-impregnated knitted Dacron aorto-iliac grafts (Quarmany *et al.*, 1998). Gelatin is a derivative of collagen that is easily degraded when applied as a graft coating, and this degradation may be exploited via modifications of coating techniques to exploit this property.

The most abundant serum proteins are albumin, fibrinogen, and IgG. They adsorb to grafts almost instantaneously following exposure to the systemic circulation. Subsequently, there is a redistribution of proteins according to each protein's relative biochemical and electrical affinity for the graft surface and their relative abundance (Vroman, 1987). Since platelets and blood cells interact predominantly with the bound proteins and not with the prosthetic material itself, the constitution and concentration of bound protein has a profound influence over the type and degree of cellular interaction with the graft. Fibrinogen, laminin, fibronectin, and vitronectin all have an arginine-glycine-

aspartate (RGD) sequence that is recognized by platelets' glycoprotein (GPIIb/IIIa) receptor and initiate platelet activation. RGD sequences are also recognized by  $\beta_2$  integrin, which directs leukocyte adhesion to the graft. Additional plasma proteins, including complement components, can also be differentially activated directly by different synthetic surfaces. For example, the generation of the monocyte chemoattractant C5a is greater following implantation of Dacron as compared to ePTFE grafts in an animal model (Shepard *et al.*, 1984). In addition, the rapid accumulation of coagulant proteins such as thrombin and Factor Xa on the luminal surface after implantation contributes to the thrombogenicity of vascular grafts.

### Porosity

The prevalence of open spaces or pores determines the porosity of a scaffold or synthetic graft, while the permeability of a graft is defined by its ability to permit passage of a substance through itself. Since ePTFE is composed of a number of solid nodes interconnected by a matrix of thin fibrils with no uninterrupted transmural spaces, it is best categorized by the distance between these nodes, which is defined as the internodal distance (IND). This spacing allows for cellular ingrowth, but transinterstitial ingrowth is not strictly a function of porosity. We have shown that the extent of ingrowth varies greatly among different biomaterials (e.g., PGA and Dacron), despite these biomaterials' having similar porosity (Greisler *et al.*, 1985).

Still, the rate of tissue ingrowth can be improved by optimizing graft porosity or permeability. Clowes *et al.* (1986) have demonstrated enhanced tissue ingrowth and complete re-endothelialization of 60- $\mu$ m or 90- $\mu$ m-internodal-distance ePTFE grafts in a baboon model. However, transinterstitial capillary ingrowth was not seen with the more commonly used 30- $\mu$ m internodal distance ePTFE. Human trials using ePTFE with these expanded internodal distances failed to show any advantage in platelet deposition as compared to standard 30- $\mu$ m-internodal-distance ePTFE grafts (Clowes and Kohler, 1991).

### Compliance

The compliance mismatch between arteries and grafts causes flow disruption *in vivo*, which may contribute to anastomotic pseudointimal hyperplasia (Abbott and Cambria, 1982). It is for this reason that various surgeons have suggested interposing a segment of vein between the synthetic graft and artery, creating a composite graft at the distal anastomosis. This has led some investigators to design more compliant grafts using more flexible materials and/or changing the parameters of graft construction to improve graft compliance. Although animal experiments have suggested concept validity, the clinical benefit of this approach remains controversial. Many factors may contribute to this confusion, including longitudinal variability in the diameter and compliance of the arterial tree and the

effect of activated endothelium on intimal hyperplasia. Further, there is a robust fibrotic response after implantation that leads compliant grafts to become in compliant after implantation; thus, even if a compliance match were attained initially, it would not likely persist. In the para-anastomotic region there are dynamic changes in compliance that vary over time. First a para-anastomotic hypercompliant zone exhibits a 50% gain in compliance; later its compliance is lessened 60% from baseline (Hasson *et al.*, 1985). It is likely that this bimodal effect limits the practical value of this approach.

### Thromboresistance

Early platelet deposition on vascular grafts is mediated by von Willebrand factor and platelet membrane glycoproteins. After adherence to a graft, platelets degranulate, releasing many bioactive substances, including serotonin, epinephrine, ADP, and thromboxane A<sub>2</sub>; these substances in turn activate additional platelets and promote a prothrombotic reaction. Activated platelets also release growth factors, such as PDGF, EGF, and TGF- $\beta$ , which promote SMC migration and proliferation as well as ECM degradation and ECM protein synthesis. In addition, platelets release monocyte chemoattractants such as platelet factor 4 and  $\beta$ -thromboglobulin, which mediate the recruitment of macrophages to the graft. Platelet deposition and activation continues chronically after graft implantation, as evidenced by increased thromboxane levels and decreased systemic platelet counts one year after Dacron graft implantation in a canine model (Ito *et al.*, 1990), and human studies have confirmed platelet adhesion to grafts up to one year after implantation.

Since the deposition and activation of platelets elicit various pathologic cascades, the thrombotic nature of the synthetic graft surface can lead to both early and late graft failure. Myriad approaches have been studied to attenuate platelet deposition, aggregation, and degranulation. Antiplatelet agents directly targeting platelet/graft-binding molecules such as platelet surface GPIIb/IIIa and different functional domains of thrombin have been shown, at least transiently, to decrease the accumulation of platelets on Dacron grafts (Mazur *et al.*, 1994). Also, the surface thromboticity of grafts can be altered experimentally, as described earlier.

Similar approaches can be utilized to decrease thromboticity by disrupting the activation of the blood system's coagulation cascade on thrombotic surfaces, such as cardiovascular stents and synthetic grafts. We have reported improved patency, thromboresistance, and the absence of intraluminal graft thrombus in heparin-analog-coated ePTFE grafts using a canine bilateral aorto-iliac artery model (Laredo *et al.*, 2004). Similarly, combined data tables of clinical data showed a decrease in subacute thrombosis with heparin-coated coronary artery stents (Gupta *et al.*, 2004). Genetic approaches to increase thromboresistance have been employed by multiple groups through the overexpres-

sion of thrombotic inhibitors. But since ECs themselves are antithrombotic, there may be limited benefit of this approach when compared to establishing a functioning endothelium.

### Resistance to Infection

Vascular graft infection is rare, but it is catastrophic when it occurs, as demonstrated by an amputation rate of approximately 50% and a reported mortality rate that ranges from 25% to 75%. In an attempt to limit this dreaded complication, penicillin and cephalosporins have been successfully bound to Dacron and ePTFE grafts and found to limit *Staphylococcus aureus* infection in animal models. Rifampin-bonded gelatin-sealed Dacron grafts have also been shown *in vitro* to lessen bacterial colonization (Vicaretti *et al.*, 1998). Intuitively, tissue ingrowth itself may also provide resistance to infection.

### Biological Modification Through Exogenous Sources

The delivery of potent angiogens or genes that promote EC-specific mitogenesis or chemotaxis on prosthetic surfaces may be used to regenerate a rapid and complete endothelium after vascular intervention. Such prosthetics could store these genes or proteins and provide a controlled expression or release of these genes or proteins locally to circulating or surrounding ECs in a cell-demanded fashion. Ideally, this kind of prosthetic could then be available as an off-the-shelf alternative to autogenous vein.

### Protein Therapy

Although tissue incorporation is a desirable process for implanted prostheses, excessive vascular cell proliferation as well as extracellular matrix (ECM) deposition can lead to intimal hyperplasia and ultimately graft failure. The ideal healing process in vascular grafts would be rapid endothelialization of blood-contacting surfaces, concomitant to a spatially and temporally limited subendothelial SMC growth and followed by phenotypic and functional differentiation of cellular components and the subsequent remodeling of a mature ECM. The recent expansion of knowledge concerning mechanisms responsible for the migration and proliferation of ECs and SMCs, angiogenesis, ECM deposition and remodeling, and physiologic parameters provides optimism for the possibility of manipulating the healing process through the directed manipulation of the microenvironment within the graft and perigraft tissue.

Since ECs have only limited capacity for regeneration, re-endothelialization of the relatively large surface areas encountered clinically exceeds the normal mitogenic capacity of surrounding ECs. Thus endothelialization requires the recruitment of ECs from sites beyond the anastomotic border via the circulation or through transinterstitial migration from the surrounding tissue and/or the vasa vasorum. This is possible under the direction of localized angiogenic stimuli, and to a limited degree this is what occurs *in vivo* as protease-driven ECM changes and local availability of

**FIG. 39.2.** Transmural induction of endothelialization by FGF-1 on prosthetic graft. Fibrin glue delivery of exogenous FGF-1 promotes ePTFE endothelialization. The untreated control is pictured on the left side at 117 $\times$ , and the FGF-1 treated graft is seen on the right at 486 $\times$ . The treated graft demonstrates robust capillary ingrowth and cellular coverage not seen in the control graft. Reprinted from Gray *et al.* (1994), pp. 600, 602, with permission from Elsevier.

growth factors stimulate ECs, SMCs, and fibroblasts to enter the cell cycle.

Platelet deposition and the perigraft inflammatory response lead to the release of many cytokines and proteolytic enzymes, which in turn incite secretion of a cascade of growth factors. Some of these growth factors are potent angiogens (e.g., VEGF and FGF), while others are angiogenic inhibitors (e.g., platelet factor 4, thrombospondin); still others (e.g., TNF- $\alpha$  and TGF- $\beta$ ) exhibit both activities.

The local delivery of growth factors or selected ECM may be utilized to promote desirable cellular events, such as endothelial ingrowth of synthetic grafts. For example, local delivery of exogenous angiogenic factors through a biologic delivery system (e.g., fibrin) may induce transmural capillary ingrowth *in vivo*, which can be the source of cells for an endothelial lining within synthetic grafts. Bioresorbable grafts may also facilitate local angiogenic responses by stimulating macrophage release of angiogenic proteins. Fibroblast growth factors, notably FGF-1 (acidic FGF) and FGF-2 (basic FGF), have potent mitogenic, chemotactic, and angiogenic activity on vascular cells. But, in order to deliver them locally to direct intimal regeneration, they require a delivery system that provides predictable local release, with bioactivities preserved over a specific interval of time. Their ability to promote endothelial ingrowth has been tested experimentally after application to grafts. Our lab has evaluated the affixation of FGF-1 to synthetic surfaces. In early attempts, FGF-1 was applied to various synthetic grafts via a fibrin glue delivery system that, due to its structural orientation and state of polymerization, had been found not to be thrombogenic (Zarge *et al.*, 1997). After delivering FGF-1 from fibrin glue to 60- $\mu$ m IND ePTFE in both canine aorto-iliac and thoracoabdominal aortic models, there was a significant increase in luminal EC proliferation, as assayed by en face autoradiography, and a more rapid development of a confluent Factor VIII–positive endothelial blood-contacting surface (Greisler *et al.*, 1992;

Gray *et al.*, 1994) (Fig. 39.2). There was also extensive trans-  
interstitial capillary ingrowth observed throughout the graft wall. Cross-sectional autoradiography did find a significant increase in subendothelial myofibroblast proliferation in these treatment grafts at one month, but this returned to baseline at later time points. Still, treated grafts developed a significantly thicker pseudointima ( $139\ \mu\text{m} \pm 178\ \mu\text{m}$  versus  $93\ \mu\text{m} \pm 89\ \mu\text{m}$  and  $67\ \mu\text{m} \pm 151\ \mu\text{m}$ ) at 140 days. In order to limit this IH response, we have developed site-directed mutants based on the FGF-1 angiogen and bioactive chimeric proteins that promote favorable characteristics, including prolonged bioactivity, EC specificity, and increased potency, while removing unfavorable characteristics, such as heparin-dependent activity and susceptibility to thrombin-induced proteolysis (Erzurum *et al.*, 2003; Brewster *et al.*, 2004).

Coimmobilization of FGF-2 and heparin in a microporous polyurethane graft by cross-linked gelatin has also been demonstrated to accelerate tissue regeneration on synthetic grafts, associated with a greater extent of endothelialization via perianastomotic and transmural capillaries ingrowth, in a rat aortic grafting model (Doi and Matsuda, 1997). A consistent neointima of approximately 40- $\mu$ m thickness with intermittent endothelialization as well as SMCs and fibroblasts underneath the luminal surface were observed in the middle portion of treatment grafts, compared to the control grafts, covered with only a fibrin layer. However, because of the cross-talk that exists in the vessel wall between ECs, SMCs, and fibroblasts, multimodal therapies that promote EC coverage while limiting activation of VSMCs or the delayed delivery of cell cycle inhibitors may be required to optimize graft healing.

### Gene Therapy

Gene therapy shares the same promise as proteins, but it may also allow sustained or controlled protein expression in a desired location that is not possible with protein formu-

lations. These qualities could obviate some of the current limitations encountered with the direct application of growth factor proteins to tissue beds for the regeneration of the endothelium.

This approach shows much promise as a delivery system, but single gene therapy trials have not yielded straightforward results. For example, although VEGF does improve endothelialization consistently, it does not reliably limit IH (and sometimes even promotes IH) in the literature. Gene therapy still requires cellular transduction or infection, and this has a variable effect on the cellular behavior. Also, controversial results have been reported in the literature related to the proliferation, adhesion, and retention of genetically modified ECs on the surface of synthetic grafts. A major concern is that genetically modified ECs display poor retention on graft surfaces *in vivo*. This was demonstrated at six weeks in canine thoracoabdominal aortic ePTFE grafts seeded with lacZ-infected ECs as compared to noninfected control ECs (Baer *et al.*, 1996). Further, Dunn (Dunn *et al.*, 1996) reported only 6% retention of ECs that had been retrovirally infected with thromboplastin on Dacron grafts after two hours of exposure to flow *in vivo*. For these reasons, little success has been documented to date concerning the long-term benefit of genetically modified EC-seeded grafts *in vivo*.

## Cells

In addition to the emphasis on the endothelialization of the flow surface, the function of other cell types, particularly the SMCs, in the vascular wall have become better appreciated. It has been suggested that ECs by themselves cannot produce a stable intima without SMCs or fibroblasts underneath. In support of this contention, tissue fragments containing multiple cell types, including venous tissue, adipose tissue, and bone marrow, have been seeded onto grafts and found to accelerate graft-healing processes. Interestingly, bone marrow cell seeding was also reported to induce an abundant capillary ingrowth in the graft wall and a rapid, complete endothelialization of the inner surface without intimal hyperplasia. Since bone marrow stem cells have the ability to differentiate in response to their microenvironment and to proliferate as well as secrete cytokines critical to their survival, they may provide a useful cell source for blood-vessel-tissue engineering.

## IV. THERAPEUTIC ANGIOGENESIS AND ARTERIOGENESIS

### Therapeutic Angiogenesis

In addition to stimulating graft re-endothelialization via transmural angiogenesis, a number of cardiovascular pathologies and surgical interventions could benefit from the ability therapeutically to stimulate new blood vessel formation (neovascularization). Peripheral vascular disease, myocardial ischemia, wound healing, and tissue engineer-

ing are just a few of the many fields that may benefit from this approach.

### Growth Factor Therapy for Angiogenesis

The process of neovascularization is controlled by a complex spatial and temporal expression of proteins, and to date most strategies have attempted to stimulate angiogenesis by injecting growth factors (as proteins) systemically or directly into target tissues. VEGF, FGF-1, and FGF-2 have been utilized frequently, reaching the point of clinical trials for the treatment of myocardial and/or peripheral limb ischemia. Many other growth factors also play a role in neovascularization and are under investigation in animal and *in vitro* models. Angiopoietins (Ang-1 and Ang-2), placental growth factor (PlGF), FGF-4, hepatocyte growth factor (HGF), ephrin-B2, and platelet-derived growth factor BB (PDGF-BB) are a few of the many other proteins with the potential to be used for therapeutic neovascularization.

Due to short protein half-lives *in vivo* and their rapid diffusion out of target tissues, growth factor therapies require high initial concentrations, and repeat injections are required in order to achieve a noticeable response. Yet sustained protein levels are most likely needed in order to form a stable microvasculature. Since it is the local microenvironment concentration that determines the structure of the resultant microvasculature (Ozawa *et al.*, 2004), these initially high concentrations can lead to demonstrable side effects, such as hyperpermeable or malformed vessels. Even sustained local concentrations may not elicit a sufficient angiogenic response, because ischemic tissue may have an altered ability to respond to growth factors (Ruel *et al.*, 2003).

### Gene Therapy for Angiogenesis

The genes of these same proteins have also been investigated as neovascularization therapies. As with gene delivery to vascular grafts, the goal of these approaches is typically local overexpression of the protein. Delivery of a single gene or protein has shown promise in animal models, but clinical results have fallen short of expectations. Overexpression of multiple proteins may have a synergistic effect on neovascularization. Placental growth factor (PlGF) combined with VEGF has been shown to be significantly more potent than each factor alone in an animal model that was refractory to a single protein (Autiero *et al.*, 2003). Combined delivery of adenovirus-mediated VEGF and Ang-1 has also been shown to promote greater perfusion and vessel stability in muscle flaps than VEGF alone (Lubiatowski *et al.*, 2002). Combined therapies may also be more effective in treatment of diseased or elderly patients who are known to have an impaired response to a single protein.

### Cellular Therapy for Angiogenesis

Cellular therapies can also be used to enhance neovascularization. ECs injected into ischemic or engineered tissues are thought to mimic vasculogenesis and to assem-

ble into capillary structures, but they may also act as sources of pro-angiogenic factors. Studies have shown that these cells can fuse with invading host vessels, recruit perivascular cells, and establish flow (Nor *et al.*, 2001) and that support cells can prolong the existence of transplanted vessels (Koike *et al.*, 2004). Here ECs seeded alone into fibronectin-collagen type I gels and implanted into mice showed little perfusion and regressed from the gels after 60 days, while ECs combined with mesenchymal precursor cells resulted in the formation of vessels that established flow through connections with the mouse circulatory system. Endothelial progenitor cells (EPCs) (S. Park *et al.*, 2004; Suh *et al.*, 2005) may also be used to increase neovascularization. These cells may have increased proliferative capacity relative to mature ECs and may be less sensitive to the short-term hypoxic conditions in tissues prior to establishing a blood flow. Injected EPCs selectively localize in ischemic tissues and increase vascular density (S. Park *et al.*, 2004). However, the mechanism for this increase is not clear. EPCs may develop into new vascular structures or may increase neovascularization indirectly by recruiting monocytes/macrophages that then secrete angiogenic factors (Suh *et al.*, 2005).

EPCs can also be genetically modified to enhance their therapeutic function. EPCs transfected to express VEGF stimulate a greater improvement in blood flow and angiogenesis in animal models of ischemia than EPCs alone (Iwaguro *et al.*, 2002). While they have a longer life than fully differentiated cells, EPCs isolated from adults have reduced telomerase activity and regenerative capacity relative to embryonic stem cells. EPCs isolated from bone marrow and transfected to express telomerase reverse transcriptase (TERT) are more resistant to apoptosis and increase neovascularization in an animal model of limb ischemia (Murasawa *et al.*, 2002).

### Arteriogenesis

Facilitating arterialization of capillary beds (arteriogenesis) rather than formation of new capillary beds (angiogenesis) may be critical to facilitating adequate perfusion needed to overcome tissue ischemia. Recent work has shown that nonviral monocyte chemoattractant protein-1 (MCP-1) gene delivery increases arteriogenesis in a rabbit ischemic limb (Muhs *et al.*, 2004), and results from clinical trials suggest that VEGF gene therapy may also stimulate arteriogenesis. Less specifically, cell delivery can also enhance arteriogenesis.

Monocytes injected intravenously into rabbits following femoral artery ligation have been shown to home to sites of ischemia and to stimulate arteriogenesis. By genetically modifying these monocytes with granulocyte-monocyte colony-stimulating factor, collateralization was increased significantly (Herold *et al.*, 2004). Although promising, monocytes are also active participants in atherosclerosis, and it may be difficult to direct arteriogenesis without concomitant atherogenic activity.

## V. TISSUE-ENGINEERED VASCULAR GRAFTS

Driven by the desire to develop an ideal vascular substitute, the construction of tissue-engineered arterial grafts has been attempted, with variable success. The potential benefits of tissue-engineered vascular grafts (TEVGs) include the creation of a responsive and self-renewing tissue graft with functional intimal, medial, and adventitial layers (including both cellular and ECM components) that can be remodeled by the body according to its needs. Such grafts may improve graft durability and reduce the potential for graft infection by lessening the foreign-body reaction and facilitating a more complete integration of the graft into the surrounding tissue.

### *In Vitro* Tissue-Engineered Vascular Grafts

Weinberg and Bell (1986) were the first to develop a TEVG *in vitro*. Using collagen and cultured bovine vascular cells, they demonstrated the feasibility of creating a TEVG, but their graft had prohibitively low burst pressures, requiring external Dacron for support. In the following decade L'Heureux *et al.* (1998) constructed a human blood vessel with an acceptable burst strength and a thromboresistant endothelium *in vitro* using cultured umbilical cord-derived human cells. But because of the immunogenic effects of the heterogeneous ECs *in vivo*, this graft, devoid of ECs, had only a 50% patency rate at eight weeks in a canine model. Since neonatal cells have a greater rejuvenative capacity, the foregoing TEVG was not considered applicable to the aged population that would most benefit from a TEVG. The prototype TEVG was created by seeding ECs onto ePTFE grafts *in vitro* and then implanting them clinically.

### Endothelial Cell Seeding

Ideally, EC-seeded grafts should have a confluent endothelial cell lining at the time of implantation, and the cells should be able to resist desquamation from shear stress after the restoration of circulation, with the more desirable aspects of their physiologic function intact. Further, the void created after desquamation should be rapidly covered by proliferating ECs in response to autocrine/paracrine release of growth factors. Since ECs normally promote thromboresistance, EC-seeded grafts have a theoretical benefit in reducing graft thrombosis. In addition, a confluent EC monolayer may also prevent the development of myointimal hyperplasia by (1) preventing the deposition of platelets, which release bioactive factors responsible for SMC migration, proliferation, and production of ECM; (2) maintaining a mechanical barrier to VSMC invasion via intimal basement membrane and the internal elastic lamina; and (3) assuming a quiescent EC phenotype that does not stimulate SMC activity.

In 1978, Herring *et al.* (1978) first reported that endothelial cell seeding onto a graft surface enhanced graft

survival. Since then, this subject has been intensively investigated. Considerable progress has been achieved, especially related to technical problems such as cell culture and retention. Initial difficulties in cell harvest, cell seeding and adhesion, and prevention of desquamation have been largely overcome. One of the early difficulties encountered was due to the relatively low cell density initially applied to the graft. Even though the cell density of the endothelial cell monolayer on a normal vein is approximately  $10^3$  ECs/mm<sup>2</sup>, an initial density of at least  $5 \times 10^3$  ECs/mm<sup>2</sup> is required for immediate confluent EC coverage of a small-caliber vascular graft after exposure to the circulation.

Since ECs adhere very poorly to synthetic graft materials, many adhesive proteins, such as fibronectin, collagen, fibrin, laminin, cell-adhesive peptides (e.g., RGD, REDV, and YIGSR), and plasma, have been applied to the graft surface to improve the seeding efficiency. Studies on the kinetics of EC loss following seeding showed that between 20% and 70% of initially adherent cells are lost during the first hour and as few as 5% were retained after 24 hours (Rosenman *et al.*, 1985). Retained cells at least partially compensate for the cell loss by migration and proliferation. Preconditioning the seeded EC monolayer with graded shear stress promotes reorganization of the EC cytoskeleton and production of ECM, which in turn enhances the EC retention at flow exposure (Ott and Ballermann, 1995). The properties of the prostheses also affect EC attachment. Dacron yields higher cell-attachment rates as compared to ePTFE when both grafts are coated with the same matrix. Polyurethane also showed better cell attachment than ePTFE.

To maximize immediate cell inoculation density, a two-stage seeding procedure is often performed, in which endothelial cells are harvested, allowed to proliferate *in vitro*, and then seeded and grown to confluence on the vascular graft prior to implantation. The disadvantages of this technique include the increased potential for infection, the alterations of EC phenotype and function, the requirement of a waiting period of three to four weeks for expansion of the cell population, and the necessity for two operative procedures.

An alternative method involves the use of microvascular endothelial cells. Small-diameter Dacron grafts seeded with enzymatically harvested omental microvascular cells in a single-stage technique showed confluent endothelial linings, larger thrombus-free surface area, and improved patency rates at one year in a canine model (Pasic *et al.*, 1994). Zilla *et al.* demonstrated increased patency and decreased platelet deposition in clinically implanted endothelial cell-seeded ePTFE femoropopliteal bypass grafts over three years as compared to unseeded grafts. And this group more recently reported an overall seven-year primary patency rate of 62.8% for 153 endothelialized femoropopliteal ePTFE grafts (Meinhart *et al.*, 2001), which is comparable to the patency rate of saphenous vein grafts in this region. However, the seeded grafts have not been reproduc-

ibly shown significantly to reduce anastomotic pseudointimal hyperplasia.

In fact the potential for IH is a major concern with EC-seeded grafts, and this has been described in a couple of case reports. In one case, bilateral above-knee grafts seeded with cephalic vein ECs developed stenosis and had to be replaced 41 months after implantation. The central part of this graft was explanted and investigated. The graft had a confluent endothelial lining on a collagen IV positive basement membrane with subintimal tissue of  $1.21 \pm 0.19$ -mm thickness (Deutsch *et al.*, 1997). The unusually thick subendothelial layer was also found in another case, in which a microvascular EC-seeded Dacron graft was placed as a mesoatrial bypass and had to be resected because of external mechanical stricture nine months after implantation (P. K. Park *et al.*, 1990).

Besides technical problems, concern exists as to the ultimate function of those endothelial cells on the graft surface, the cells having been injured by the process of manipulation and/or chronic exposure to a nonphysiologic environment. Unlike their uninjured counterparts, injured endothelial cells produce a variety of procoagulants, such as von Willebrand Factor, plasminogen activator inhibitor, thrombospondin, and collagen. Higher levels of PDGF and bFGF have also been measured in EC-seeded grafts; this is particularly concerning, given their potential role in stimulating the migration and proliferation of SMCs, which can lead to IH.

### Arteries Engineered *In Vitro*

The two main components of arterial generation *de novo* are the cells and their scaffolds. These components are not separable in practice, but they are separated in this chapter to emphasize their respective contributions.

There is much discussion about the proper cells to use for cell seeding *ex vivo* or cell homing *in vivo*. The EC is the most fastidious vascular cell to grow, and heterogeneous ECs are highly immunogenic. Therefore, in the absence of immunosuppression, autogenous ECs are currently a requirement for TEVG. TEVG media and adventitia can be created by using vascular smooth muscle cells or fibroblasts with or without exogenous matrix scaffolding. These cells can be harvested from the patient in need. But, since these patients are typically older, with significant comorbidities, their cells (particularly VSMC and ECs) may not retain sufficient doubling capacity necessary to generate these TEVGs. In part this may be due to the loss of telomere length that occurs with aging.

In support of this hypothesis, Niklason *et al.* have demonstrated an increase in the population doublings of adult VSMCs through retroviral infection with the telomerase reverse transcriptase subunit (hTERT), without evidence of inducing cellular transformation (Poh *et al.*, 2005). However these arteries have unacceptably low bursting strength, and this is probably because hTERT infection did not remediate

the stunted production of essential ECM proteins (e.g., collagen) that confer vessel strength in these transformed aged cells. Using a clinically relevant aged fibroblast-derived media, L'Heureux demonstrated a TEVG that has suitable bursting strengths at insertion, has a functional endothelium, and demonstrates mechanical stability in a variety of animal models out to eight months (L'Heureux *et al.*, 2006). These functional characteristics of a TEVG provide proof of concept of the functional promise of this approach, begun approximately 100 years ago.

Clinical success has been seen when using a TEVG for vessel replacement in the venous system, which is potentially less tenuous hemodynamically. These TEVGs have been implanted in 42 pediatric patients with congenital heart defects. To date these grafts have been resistant to aneurysmal dilatation and have had superb patency (Shin'oka *et al.*, 2005).

Various cellular and acellular approaches to TEVG scaffolds have also been pursued, and the challenge of the scaffold begins with providing satisfactory retention of cells *in vivo* or *ex vivo* in clinically relevant bioreactors and promoting optimal phenotypic characteristics of those cells. In addition, the scaffold or resulting vessel must have sufficient bursting strength to withstand the physiologic stresses of the circulation. After implantation this scaffold will undergo remodeling, which can lead to aneurysmal dilatation and subsequent graft rupture. Niklason *et al.* (1999) reported encouraging results with a graft produced by seeding SMCs onto PGA scaffolds that were sodium hydroxide modified to promote cell attachment. This graft was cultured in an *in vitro* pulsatile radial stress environment for eight weeks prior to implantation. These grafts showed contractile responses to serotonin, endothelin-1, and prostaglandin  $F_{2\alpha}$ , and they expressed the SMC differentiation marker, myosin heavy chain. Further, the grafts cultured under pulsatile conditions produced more collagen than those grown without pulsatile stress and exhibited a mechanical strength comparable to native human saphenous veins; this graft ruptured at  $2150 \pm 909$  mmHg versus  $1680 + 307$  mmHg for saphenous vein. Autologous ECs were seeded onto the luminal surface and were cultured for three more days before implantation. Four of the grafts were then implanted into swine saphenous arteries, of which two were generated under pulsatile stress and two under static condition. Two pulsed grafts remained patent up to the fourth week without dilation or rupture, while two nonpulsed grafts thrombosed after three weeks; the polymer remnants were no longer visible at four weeks.

Decellularized tissue scaffolds are appealing because they are already composed of native vascular extracellular matrix proteins that exhibit reasonable structural characteristics as well as providing instructive cues for cellular ingrowth. Using bone marrow-derived cells incubated on decellularized canine carotid arteries, Byung-Soo Kim *et al.* demonstrated cellular incorporation into the scaffold and

subsequent differentiation of these cells into endothelial and vascular smooth muscle cells and subsequently into three distinct vessel layers (Cho *et al.*, 2005). Others have used a more focused approach and induced or applied endothelial progenitor cells (EPCs) into similar scaffolds, with promising results. The benefit of EPCs include a robust replication potential ideal for a TEVG, and these cells acquire mature endothelial cell markers and function upon seeding into TEVGs (Kaushal *et al.*, 2001). These attributes may be further augmented by gene therapy.

Using biologic gels, such as those composed of type I collagen or fibrin, one can promote tissue ingrowth and direct remodeling in a bioreactor, thereby promoting favorable characteristics, such as improved mechanical strength and vessel reactivity over time (Swartz *et al.*, 2005). Such approaches are easily modified by the addition of growth factors with refined delivery systems in order to enhance and sustain cellular ingrowth (Ehrbar *et al.*, 2004). Further refinement of these scaffolds can mimic the differential mechanical properties of the intimal and medial arterial layers.

### In Vivo Tissue-Engineered Vascular Grafts

Current clinically available synthetic vascular grafts, composed of ePTFE, Dacron, or polyurethane, are permanent prostheses within the host after implantation. Theoretically, it is possible with bioresorbable materials to stimulate a rapid and controlled ingrowth of tissue to assume the load bearing sufficient for resistance to dilation and to incorporate cellular and extracellular components with desirable physiologic characteristics to form a new artery *in vivo*, whereby the synthetic material itself would cease to be necessary following tissue ingrowth. Still, the limited regenerative capacity of aged or diseased cells discussed earlier may also compromise cellular ingrowth *in vivo*.

### Bioresorbable Grafts

Aneurysmal dilatation of bioresorbable grafts can be expected to occur after sufficient degradation of the graft material and prior to adequate cell growth. The first published report of a fully bioresorbable graft was by Bowald in 1979 (Bowald *et al.*, 1979) and described the use of a rolled sheet of Vicryl (a copolymer of polyglycolide and polylactide). However, these early grafts were prone to aneurysmal dilation and rupture. We have determined that 10% of the PGA grafts have aneurysmal dilation within the first three months after implantation and that this does not increase over the next nine months, suggesting that the critical time for the development of aneurysms is during prosthetic resorption prior to the ingrowth of tissue with a sufficient strength to resist hemodynamic pressures. These studies also demonstrated the ability of bioresorbable grafts to support sufficient cellular ingrowth. Here, four weeks after implantation, these 24-mm by 4-mm grafts contained an inner capsule with a confluent layer of endothelial cells and

myofibroblasts amidst dense collagen fibers (Greisler, 1982). Similarly constructed and implanted Dacron grafts demonstrated an inner capsule containing solely fibrin coagulum with minimal cellularity. Macrophage infiltration and phagocytosis paralleled the resorption of PGA, which was totally resorbed at three months.

In order to limit this catastrophic outcome, several approaches have been developed. One is to combine the bioresorbable material with a nonresorbable material in order to retain a mechanical strut. Another solution involves the combination of two or more bioresorbable materials with different resorption rates so that the more rapidly degraded material evokes a rapid tissue ingrowth while the second material provides temporary structural integrity to the graft. Thirdly, growth factors, chemoattractants, and/or cells can be applied to the graft to enhance tissue ingrowth, structure, and organization.

Using a more slowly resorbed compound, polydioxanone (PDS), we encouraged similar endothelialization of the regenerated luminal surface as earlier and prostacyclin and thromboxane production in similar concentrations as control rabbit aortas. PDS was retained up to six months, and only 1/28 PDS grafts exhibited aneurysmal dilation, with explant times as late as one year. The explanted specimens of these PDS grafts also demonstrated biomechanical characteristics similar to those of native arteries, being able to withstand static bursting pressures of 6000 mmHg and 2000 mmHg mean pulsatile pressure without fatigue (Greisler *et al.*, 1987).

Using the differentially resorbed approach with composite grafts woven from yarns of 74% PG910 and 26% PDS, we reported a one-year patency rate of 100% with no aneurysms in the rabbit aorta model. The PG910 was totally resorbed by two months and the PDS by six months. The regenerated arteries withstood 800 mmHg of pulsatile systolic pressure *ex vivo* without bursting, and a confluent, functional, von Willebrand factor–positive endothelial cell layer over circumferentially oriented smooth muscle–like myofibroblasts formed in the inner capsule of both these grafts. Additional experiments were done with a variety of resorbable materials in combination with Dacron (Greisler *et al.*, 1986). The results demonstrated that transanastomotic pannus ingrowth is not a critical source of cells replacing bioresorbable vascular prostheses. Rather, trans-*interstitial* ingrowth of myofibroblasts, capillaries, and endothelial cells is the principle mechanism. In addition, tissue ingrowth into all tested lactide/glycolide copolymeric grafts was observed to parallel the kinetics of macrophage phagocytosis and prosthetic resorption. *In vivo*, the rate of cell proliferation and collagen deposition in the inner capsule also paralleled the kinetics of macrophage-mediated prosthetic resorption (Greisler *et al.*, 1993). These studies also confirmed both the inhibitory effect of Dacron and the stimulatory effect of lactide/glycolides on tissue ingrowth and inner capsule cellularity. As described earlier in this chapter, activated macrophages release a variety of

growth factors, including PDGF, interleukin-1, basic FGF, TGF- $\beta$ , and tumor necrosis factor. Since the phagocytosis of various biomaterials can lead to macrophage activation, rabbit peritoneal macrophages were cultured in the presence of polyglactin-910, Dacron, or neither and the mitogenic activity in the resulting conditioned media compared using growth assays of quiescent BALB/c3T3 fibroblasts, rabbit aortic SMCs, and murine capillary ECs. The media of the macrophages grown in the presence of the bioresorbable polymer stimulated significantly more proliferation in all cell types than did the media of the macrophages grown in the absence of the material or in the presence of Dacron, with 60–80% of the mitogenic activity blocked by immunoprecipitation using an FGF-2 antibody (Greisler, 1991; Greisler *et al.*, 1996).

Partially resorbable grafts have also been investigated. Since Dacron was found to inhibit the macrophage-mediated arterial regeneration stimulated by the resorbable component PG910, polypropylene was evaluated as a nonresorbable component because of its high tensile strength, low fatigability, low degradation *in vivo*, and minimal inhibitory effect on cellular regeneration of grafts (Greisler *et al.*, 1992). Composite grafts constructed from yarns containing 69% PG 910 and 31% polypropylene implanted into rabbit and dog arteries again demonstrated superb results without aneurysmal dilation. Galletti (Galletti *et al.*, 1988) used Vicryl prostheses coated with retardant polyesters to protect the Vicryl temporarily from hydrolytic and cellular degradation. When implanted into the canine aorta, prosthetic resorption was noticed at four weeks and was complete by 24 weeks. No coated grafts developed aneurysmal dilatation, whereas one of the uncoated grafts ruptured. He theorized that the low pH generated in the microenvironment of the degrading bioresorbable polymers, such as polyglycolide and polylactide, stimulate macrophages to secrete growth factors that induce fibroblast proliferation. In separate experiments, another group evaluated grafts prepared from a mixture of 95% polyurethane and 5% poly-lactide (van der Lei *et al.*, 1987). They found that only relatively compliant grafts that induced circumferential smooth muscle development contained elastin and remained mechanically stable without dilating. They concluded that modifications of the graft preparation, including smooth muscle cell seeding, help enhance optimal orientation of the smooth muscle cells and prevent aneurysm formation.

### The Living Bioreactor

Cambell *et al.* have developed a modification of the Sparks' mandrel to create a TEVG. Here they utilize the abdominal peritoneum's reaction to foreign bodies as a living bioreactor (Hoenig *et al.*, 2005). After the graft has matured, it is removed from the mandrel and inverted; this creates a TEVG with a mesothelial inner lining. This graft's resistance to aneurysmal dilatation and rupture has not been proven to date.

**FIG. 39.3.** Three-dimensional *in vitro* induction of a capillary network. Robust capillary formation can be induced in ECs stimulated with angiogenic growth factors in a three-dimensional fibrin matrix. **(A)** Spherical induction of a radially oriented capillary network from an EC aggregate induced by sustained low-dose FGF-1 (1 ng/mL). **(B)** When two EC aggregates are in proximity to each other, the EC sprouts are preferentially directed toward each other.

### Cellular Recruitment

Since autogenous cells cannot populate a scaffold by migration or proliferation alone, they must be recruited internally via circulating ECs or EPCs or externally from the surrounding tissue or exogenous source through angiogenic ingrowth during tissue incorporation of the graft. In addition to the benefit provided by the localization of cells, transmural ingrowth provides for cellular perfusion that extends beyond the distance supplied by simple diffusion (100  $\mu\text{m}$ ). We are currently designing three-dimensional capillary constructs (Fig. 39.3) that could provide grafts with the cellular and metabolic infrastructure requisite for the creation of a living TEVG through the induction of a vasa vasorum, which can be incorporated into preexisting capillary networks (inosculation). Proof of concept of this approach has been demonstrated in cardiac sheet grafts (Sekiya *et al.*, 2006). This induction can obviously be supplemented by the delivery of angiogenic proteins or genes to these constructs. With further research, a small-diameter, totally resorbable vascular graft may be able to improve the current dismal long-term patency rates of small-caliber grafts.

## VI. ENDOVASCULAR STENTS AND STENT GRAFTS

Endovascular stents were conceptualized prior to the introduction of angioplasty in 1969, and they have enjoyed increasing popularity in recent years. They have improved the durability of endovascular treatments and led a paradigm shift away from the traditional operative approach to vascular disease. Angioplasty, stents, and stent grafts are all endovascular interventions; they minimize the size of incisions, decrease lengths of hospital stays, and may confer some short-term survival benefit acutely after intervention. With over 1.5 million percutaneous coronary interventions occurring each year and a prevalence of in-stent stenosis ranging from 15% to 60% of patients, there is little wonder that much interest has been paid to the drug-eluting stent (DES). But DES release broadly suppressive drugs to the surrounding tissue in order to limit neointimal stenosis, and they likely retard myointimal thickening rather than

facilitate healing. This may be sufficient for short-term benefit but may compromise the long-term durability of these vascular interventions. Long-term durability is likely to become more critical in the coming years because of the improved mortality rates in patients with cardiovascular disease. Thus it is critical to avoid complacency in clinical thinking, for what comprises a good result today is dependent on mortality rates that may not be applicable to today's patients. We firmly believe that promoting healing and not limiting the adverse effects of healing will provide for durable results.

### Tissue-Engineered Cardiovascular Stents

There are three basic types of stents: balloon-expandable stents, which need balloon inflation to expand the stent into the arterial wall; self-expanding stents, allowing delivery in a collapsed form, with the stent expanding to its predetermined size after release from the delivery device; and thermal expanding stents, made by shape-memory metal alloys, which exist in an easily manipulated form and which restore their memorized shape at a certain transition temperature. All these stents have been successfully used in iliac arteries, with a two-year patency of approximately 84%. Improved endothelialization has also been reported using VEGF gene application to a modified metal stent (Walter *et al.*, 2004), and, although stenting itself has quickly become an important member of the endovascular armamentarium, the development of biodegradable stents has progressed slowly, mostly due to difficulties in replicating the properties of stainless steel stents (Serruys *et al.*, 2006). Still, the promise of cell-demand sustained drug delivery in biodegradable stents has led to a renewed interest in this approach. Currently preliminary evidence supports the short-term stability of these stents and the ability of these stents to deliver bioactive agents to the vessel lumen, providing proof of concept for this approach.

### Tissue-Engineered Stent Grafts

Stent grafts are a collapsible hybrid product composed of either Dacron or ePTFE, with stents providing radial support; they are delivered intravascularly to patients' large

vessels like cardiovascular stents. These stent grafts maintain flow through their lumen and are commonly used to exclude flow into aneurysmal portions of arteries. Theoretically, the graft creates a barrier to exclude diseased arterial wall and provides a smooth flow conduit, while the stent support affixes the graft and may enhance luminal patency by resisting external compression. Stent grafts are delivered endovascularly, and since endovascular intervention reduces early operative morbidity and mortality, they have considerable consumer interest. However, the benefits of this approach over traditional operations is not clear, and it appears that outcomes are similar to those of the more traditional operative approach two years after intervention or operation. Further, a large study subgroup of nonoperative candidates failed to demonstrate a survival benefit from endovascular repair in these patients as compared to watchful waiting (EVAR Trial Participants, 2005).

Yet the rapid improvements in stent grafts will likely lead to improved durability and decreased frequency of reintervention. Therefore they will likely have a defined role in the treatment of patients with cardiovascular disease. For this reason it is important to define the known differences in healing between stent grafts and traditional bypass grafts.

Compliance changes between stent/unsupported graft/artery interfaces yield a remarkable hemodynamic disturbance. Also, delivery procedures, like balloon dilatation, may alter both graft intrinsic characteristics such as porosity and wall thickness as well as create mechanical injury to the surrounding artery. In addition, unlike conventional bypass, the endovascular graft is placed within the lumen of arteries with perigraft exposure to diseased arterial intima or to thrombus. All these factors change the healing characteristics of stent grafts as compared to synthetic grafts. An inflammatory reaction and progressive thickening of neointima have been observed in both ePTFE- and Dacron-based stent grafts. When comparing endovascular grafts to conventional bypass grafting using a canine iliac artery model, endovas-

cular stent grafts composed of ePTFE grafts and balloon-expandable stents resulted in both a greater rate of endothelialization as well as an approximately five-times-thicker neointima in the midportion of the graft and a higher percentage of stenosis at the distal anastomosis when compared to conventional ePTFE grafts (Ohki *et al.*, 1997). Pathological remodeling has also been reported after anchoring to the arterial wall, and it has been reported that stent placement may cause a variety of flow disturbances. The stent components themselves also stimulate a nonspecific inflammatory reaction and induce neointimal formation, and tissue-engineered approaches, including cell seeding with genetically modified cells, may limit these complications (Panetta *et al.*, 2002; Eton *et al.*, 2004). The accumulation of experience, optimization of devices, and a better understanding of resultant pathological processes will likely allow the easy transfer of the recent advances in tissue-engineered grafts and vessels to stent grafts. This transfer is probably critical to enhancing their durability over time.

## VII. CONCLUSION

Much progress has been seen in recent years, and yet old things also become new again. As this publication comes to print there is renewed interest in the TEVG theorized by Carrel in the last century as well as in the use of biodegradable grafts. Currently, it is not correct to proclaim TEVGs either the promise of the future or a remnant of the past. Similarly, tissue-engineered approaches to promoting graft healing continue to provide scientific successes and clinical limitations. One can only hope that the successes seen with EC-seeded ePTFE can be translated to patients worldwide in the near future. As more patients live with cardiovascular disease than die from it, there is little doubt that promotion of graft healing will be more effective than inhibition of pathologic processes like IH. Still, for patients who are unlikely to live long enough to realize that benefit, inhibition of IH may be adequate. Thus both approaches may coexist for the near future.

### I. INTRODUCTION

Heart valve disease is a considerable medical problem around the world. The treatment for end-stage heart valve disease is valve replacement; however, the best current replacement heart valves suffer from significant shortcomings. Promising alternatives to current replacement heart valves are being developed in the field of tissue engineering. This multidisciplinary effort comprises the areas of tissue biomechanics, immunology, injury response, cellular and tissue development, and the chemical, physical, pharmacological, and genetic manipulation of both cells and biomaterials. Moreover, underpinning these advanced methodologies is a concerted effort focused on understanding the relationships of structure to function in normal and pathological tissues. In the development of a substitute tissue-engineered heart valve, significant advances have been made in several of these areas, including the development of different cell sources and cell-seeding techniques, advancements in polymeric and natural scaffold design, and the introduction of bioreactors — biomimetic devices capable of biochemically and biomechanically modulating the *in vitro* development of tissue-engineered neotissue. This chapter highlights the need for a tissue-engineered option in heart valve replacement and reviews past and ongoing work in the field. The fundamental heart valve structure, function, and disease are described, including a review of

the research leading to the development of a tissue-engineered heart valve and the challenges that remain.

### II. HEART VALVE FUNCTION AND STRUCTURE

The heart valve's physiological function is to maintain unidirectional, nonobstructed blood flow without damaging blood elements, causing thromboembolism, or placing excessive mechanical stress on the leaflets and cusps. The native heart valve is remarkably well designed to perform this function. This ability comes from an almost perfect correlation of structure with function, allowing the valve to reduce stress on the cusps and supporting tissues while enabling it to endure the wear and tear of billions of repetitive deformations (Schoen and Levy, 1999). There are four valves in the human heart, two semilunar and two atrioventricular. The semilunar heart valves include the structurally similar aortic and pulmonary valves; the atrioventricular heart valves consist of the tricuspid and mitral valves (Breuer *et al.*, 2004). The following passages describe the relation of structure to function in the semilunar valve from a macroscopic (tissue) to a microscopic (cellular) scale.

Grossly, the semilunar heart valves comprise three thin cusps that open easily when exposed to the forward blood flow of ventricular systole and then rapidly close under the

**FIG. 40.1.** Histological cross section of a heart valve, revealing the ventricularis, spongiosa, and fibrosa sections of the valve. Also shown are interstitial cells and endothelial cells.

minimal reverse flow of diastole (Schoen and Levy, 1999). The structure of the valve is such that these cusps are uniquely suited to deal with large forces and unidirectional flow. In the aortic valve, these cusps, simply called the *left*, *right*, and *noncoronary aortic valve cusps*, are attached to the aortic wall by a thick base known as the *commissures*. Despite the large forces applied, prolapse is prevented by substantial coaptation of the cusps (Rabkin-Aikawa *et al.*, 2005). In addition, these structural elements are anisotropically oriented in the tissue plane, resulting in disproportionate mechanical properties of the valve cusps, with greater compliance in the radial as opposed to the circumferential direction. This compliance allows the cusp thickness of the aortic valve to vary from 300 to 700  $\mu\text{m}$  throughout the course of the cardiac cycle (Rabkin-Aikawa *et al.*, 2005) and decreases the impedance of flow. Further structural specializations that occur are lengthwise folding of collagen fibers and the orientation of collagen bundles in the fibrous layer toward the commissures. This reduces sagging in the cusp centers and conserves maximal coaptation, thereby preventing regurgitation from occurring. Thus, both the macroscopic valve geometry and the fibrous network inside the cusps work to transfer the stresses caused by the diastolic force to the aortic wall and annulus.

Microscopically, the semilunar heart valve comprises three layers: the fibrosa, ventricularis, and spongiosa, as shown in Fig. 40.1. The main constituents of the valvular extracellular matrix (ECM) of these layers are collagen (60%), proteoglycans (20%), elastin (10%), and some glycoprotein (Kunzelman *et al.*, 1993). It is the unique extracellular structural features within these layers that produce the specialized biomechanical profile necessary for proper function (see Fig. 40.2). Most of the mechanical strength of the valve is provided by the collagen, which is composed primarily of type I, type III, and some type V collagen (Cole *et al.*, 1984). The fibrosa, below the sinus surface, is composed predomi-

nantly of crimped, densely packed collagen fibers arranged parallel to the free edge of the cusp. The elastin of a heart valve forms an encompassing matrix that binds the collagen fibrous bundles throughout the heart valve. In this way, the elastin–collagen hybrid forms a larger network of interconnecting collagen fibers (Scott and Vesely, 1995). The ventricularis on the inflow surface is composed of collagenous tissue with radially aligned elastin fibers. Meanwhile, the centrally located spongiosa is composed of proteoglycans that have glycosaminoglycan (GAG) side chains. Matrix molecules can form covalent cross-links with the GAG side chains, thereby supporting other components of the ECM (Flanagan and Pandit, 2003).

### III. CELLULAR BIOLOGY OF THE HEART VALVE

#### Valvular Endothelial Cells

Two main cell types are present in the heart valve: a covering layer of valvular endothelial cells (VECs) and inner valvular interstitial cells (VICs). Endothelial cells are critical to circulatory function and blood–tissue interaction. They also play a significant role in metabolism, synthesis, and the maintenance of homeostasis. Endothelial cells form a non-thrombogenic blood–tissue interface, have an interactive role in inflammatory and immune reactions, modulate the proliferation of other cell types, and make up the endothelium, a semipermeable membrane that regulates the transfer of large and small molecules through the vascular wall (Rabkin-Aikawa *et al.*, 2005).

VECs have an active role in the heart valve. They can respond to changing stimuli by altering their normal functions and by phenotypically expressing new, inducible properties through a process known as *endothelial activation*. Cytokines and hemodynamic forces are two examples of factors that induce endothelial activation. Once activated, the VECs produce other cytokines, chemokines, adhesion molecules, growth factors, and vasoactive molecules. This molecular cascade can result in vasodilation, vasoconstriction, or the production of procoagulant and anticoagulant moieties, major histocompatibility complex molecules, and a variety of other biologically active molecules. When the endothelium is functioning well, these factors are in equilibrium and the vessel can respond correctly to various stimuli. When the endothelium is not working properly, a form of endothelial activation known as *endothelial dysfunction* occurs, resulting in a surface that is adhesive to inflammatory cells or thrombogenic (Rabkin-Aikawa *et al.*, 2005). Also, a significant amount of endothelial cell phenotypic variation is associated with the different mechanical stresses of different anatomic locations. For example, endothelial cell populations developed from arterial sites, as opposed to venous sites, have significantly dissimilar characteristics (Shin *et al.*, 2001). This is also true in the heart valve, where researchers have found that the endothelium from aortic valves and human pulmonary valves

**FIG. 40.2.** (A) Schematic representation of the cuspal configuration and architecture of collagen and elastin in systole and diastole. (B) Stress-strain plot of biomechanical cooperativity between elastin and collagen during valve motion. During opening, elastin extends at minimal load during extension of collagen crimp and corrugations. Near full closure, when the collagen has fully unfolded, the load-bearing element shifts from elastin to collagen, and stress rises steadily while coaptation is maintained. In systole, elastin restores the contracted configuration of the cusp. A and B: Reproduced with kind permission from Schoen (1997).

have different phenotypic expression (Rabkin-Aikawa *et al.*, 2004).

Not surprisingly, there are substantial data suggesting that VECs differ from other types of endothelial cells in many ways. A recent report has suggested that the response of the endothelium to flow is different in the valves than in the aorta (Butcher *et al.*, 2004). Other investigators are beginning to propose the possibility of significant phenotypic diversity, even between the endothelium on the inflow and outflow aortic valve surfaces (Davies *et al.*, 2004).

### Valvular Interstitial Cells

While valvular endothelial cells' primary importance is their interaction with the blood and surrounding environment, valvular interstitial cells are believed to be the principal component in the maintenance of valvular structure (Flanagan and Pandit, 2003). VICs are elongated in shape and have many long, slender processes that extend throughout the valvular matrix (Filip *et al.*, 1986). By interconnecting, these processes create a three-dimensional network that permeates throughout the valve and is closely associated with the valve's ECM (Chester *et al.*, 2000, 2001).

It has been proposed that two morphologically and structurally distinct populations of VICs exist, the first having contractile characteristics of pronounced stress fibers, and the other having secretory characteristics, with pronounced rough Golgi apparatus and endoplasmic reticulum (Filip *et al.*, 1986; Zacks *et al.*, 1991; Flanagan and Pandit, 2003). In addition, VICs may have a functional capacity that extends even beyond the realm of fibroblast matrix secretion (Filip *et al.*, 1986). Specifically, it has been proposed that some VICs are capable of contracting, thereby sustaining a limited intrinsic valvular force while withstanding hemodynamic forces (Mulholland and Gotlieb, 1996). This is supported by data indicating that some VICs express both cardiac and skeletal contractile proteins (Roy *et al.*, 2000) and by observations that valve leaflets contract when exposed to a variety of vasoactive agents.

VICs are also of central importance in the valve's repair and maintenance operations (Flanagan and Pandit, 2003). The constant and rigorous mechanical movement of valves results in valvular damage and an ongoing regenerative process vital to sustained function (Schneider and Deck,

**FIG. 40.3.** Photograph of a tissue-engineered leaflet in lamb 11 weeks after implantation. Reproduced, with kind permission, from Shinoka (2002).

1981; Henney *et al.*, 1982). This is discussed further in the following sections.

## IV. HEART VALVE DYSFUNCTION AND VALVULAR REPAIR AND REMODELING

### Heart Valve Dysfunction

The American Heart Association has estimated that 87,000 heart valve replacement procedures were performed in the United States in 2000, and nearly 275,000 procedures are performed worldwide annually. Heart valve disease caused 19,737 deaths in the United States in 2000. The pathology of heart valve disease manifests itself in two ways: stenosis and insufficiency. Stenosis occurs when the valve does not completely open resulting in reduced forward flow, while insufficiency is the backflow of blood due to incomplete valvular closure (Rabkin-Aikawa *et al.*, 2005; Rabkin and Schoen, 2002; Flanagan and Pandit, 2003).

The causes and clinical frequency of heart valve dysfunction are not uniform. The most prevalent clinical problem is aortic stenosis, which usually occurs due to dystrophic calcification of the aortic valve cusps and annulus. In mitral valve stenosis the principal cause is deformity, which in most cases precipitates many years after an onset of rheumatic fever. Chronic aortic insufficiency is less common and is caused by aortic root dilation, resulting in distended and outwardly bowed commissures as well as impaired cuspal coaptation. In the tricuspid and pulmonary valves, the leading causes of dysfunction are congenital deformities. Of course, the physiologic function of any of the four cardiac valves can at any time be altered by endocarditis, an infection of the intercardiac structures. Endocarditis can destroy valve tissue in a matter of weeks and generally results in valvular insufficiency (Rabkin-Aikawa *et al.*, 2005).

### Valvular Repair and Remodeling

Valvular injury stimulates interstitial cell proliferation, migration, and apoptosis. The early events in valve repair are prominently characterized by the migration and proliferation of interstitial cells (Lester *et al.*, 1992; Lester and Gotlieb, 1988). This migration is likely governed by a series of events, including the activation of integrins and cell surface heterodimeric receptors that control cell-ECM and cell-cell adhesion. Furthermore, signaling mechanisms determine the allotment and activity of cytoskeleton proteins that orchestrate the cell spreading, contraction, and translocation typically involved in wound healing (Meredith and Schwartz, 1997; Woodard *et al.*, 1998; Rabkin-Aikawa *et al.*, 2005). Phenotypic changes of the interstitial cells themselves may also play a significant role. Recent investigations have suggested that VICs activate from a quiescent form in equilibrium to help determine the valve's biomechanical response when exposed to a new mechanical environment (Schoen, 1999; Rabkin-Aikawa *et al.*, 2005). In this manner, the VIC phenotype is determined by wall stresses in the valve leaflets. For example, in leaflets from patients with myxomatous mitral valve degeneration, interstitial cells express features of activated myofibroblasts (Rabkin *et al.*, 2001).

It is thought that VIC-matrix interactions play an important role in regulating interstitial cell-based remodeling, including the induction of cell migration, the secretion of ECM components, and the secretion of proteolytic enzymes — all critical functions in tissue repair. More specifically, enzymes such as interstitial collagenases, gelatinases, and other matrix metalloproteinase (MMP) enzymes have been localized in all four heart valves (Dreger *et al.*, 2002). In the heart valve's connective tissue, MMPs and tissue inhibitor metalloproteinases (TIMPs) count heavily in tissue remodeling and regeneration (Flanagan and Pandit, 2003), along with a number of other physiological and pathological processes (Nelson *et al.*, 2000; McCawley and Matrisian, 2001; Galis and Khatri, 2002). The interaction of TIMP, MMP, and their regulators are particularly important in cardiac and vascular remodeling (Rabkin-Aikawa *et al.*, 2005). The interstitial collagenases MMP-1 and MMP-13 mediate the preliminary phase of collagen degradation by disassembling the native helix of the fibrillar collagen. The resulting collagen fragments are then accessible to further proteases, such as gelatinases or elastases like Cathepsin K, for further catabolism (Krane *et al.*, 1996).

The pattern of TIMP and MMP expression in normal valves is highly specific (Dreger *et al.*, 2002). Excessive levels of MMP proteolytic enzymes, such as collagenases, gelatinases, and cysteine endoproteases (cathepsin S and K) overregulated by VIC, may cause collagen and elastin degradation, ultimately resulting in weakness of heart valve leaflets. Many investigations have hypothesized that the valve's own cells may cause ECM degradation in some

degenerative diseases; in some heart valve pathologies an overexpression of MMPs can be detected (Rabkin *et al.*, 2001). This suggests that these cells are somehow being stimulated to produce and secrete soluble extracellular messengers that prompt indigenous cells to degrade the matrix. One such messenger is cardiac catabolic factor, derived from porcine heart valves and found to stimulate collagen and proteoglycan breakdown *in vitro* (Decker and Dingle, 1982). The mechanism of action and the importance of MMPs/TIMPs in valve tissue morphogenesis, repair, and remodeling remain to be investigated further. It is very probable that proteolytic enzymes play a significant role in matrix remodeling in tissue-engineered heart valves (Rabkin-Aikawa *et al.*, 2005).

### Heart Valve Replacement

Standard treatment for end-stage valvular dysfunction is heart valve replacement. The first successful implantation of a heart valve in a human was performed in 1952 (Hufnagel *et al.*, 1989). Throughout the following decades, surgeons saw more than 80 new designs of prosthetic heart valves (Vongpatanasin *et al.*, 1996). Like most medical devices, heart valve substitutes have experienced a progressive technological evolution; modifications have been made and new designs introduced to address specific deficiencies in earlier devices. The classification and fundamental technologies, however, remain the same: prosthetic heart valves are either mechanical, composed of purely synthetic components, or bioprosthetic, containing biological components. Slightly more than half of the world's implanted valves are mechanical; the remainder are bioprosthetic (Butany *et al.*, 2003). While each type of valve has (generally) improved the quality and length of life for its recipients, many problems persist.

Fifty to sixty percent of all patients will experience prosthesis-associated problems requiring reoperation within 10 years following initial heart valve replacement (Bloomfield *et al.*, 1991; Hammermeister *et al.*, 1993). The overall frequency of complication is similar for bioprostheses and mechanical prostheses. Four types of valve-related complications are most common: (1) thrombosis, thromboembolism, and secondary anticoagulation-related hemorrhage; (2) prosthetic valve endocarditis; (3) structural dysfunction, including failure or degeneration of the prosthetic biomaterials; and (4) nonstructural dysfunction, including complications arising from technical difficulties during surgical implantation, such as perivalvular leak and biological integration (Grunkemeier and Rahimtoola, 1990; Bloomfield *et al.*, 1991; Hammermeister *et al.*, 1993; Jamieson, 1993; Turina *et al.*, 1993; Schoen, 1995; Edmunds *et al.*, 1996; Vongpatanasin *et al.*, 1996; Schoen and Levy, 1999). Each type of valve has its own unique set of advantages and disadvantages.

### Mechanical Heart Valves

The mechanical heart valve has excellent durability, due to the mechanical properties of the synthetic materials used

to construct them. Unfortunately, these synthetic materials also possess poor biocompatibility. Specifically, mechanical prosthetic valves are believed to increase the risk of thromboemboli and thrombotic occlusion. This is caused by the lack of an endothelial lining and the flow abnormalities that result from a rigid outflow structure (Grunkemeier and Rahimtoola, 1990; Jamieson, 1993; Turina *et al.*, 1993; Schoen, 1995; Vongpatanasin *et al.*, 1996; Cannegieter *et al.*, 1994). To reduce this risk, chronic anticoagulation therapy is necessary for all recipients of mechanical valves. Systemic anticoagulation, however, increases the potential for serious hemorrhagic complications (Cannegieter *et al.*, 1994). Thus, the combined risk of hemorrhage secondary to anticoagulation and thromboembolic complications constitutes the principal disadvantage of mechanical prosthetic heart valves. In the absence of antithrombotic therapy, meta-analysis found the occurrence of a major embolism to be four per 100 patient years. When antiplatelet therapy was administered this risk was 2.2 per 100 patient years, and with coumadin therapy the risk was reduced to one per 100 patient years (Cannegieter *et al.*, 1994). The incidence of major bleeding in coumadin-treated patients, however, was 1.4 per 100 patient years and increased significantly with the addition of antiplatelet therapy (Cannegieter *et al.*, 1994). An additional nontrivial issue is that mechanical replacement valves are more susceptible to serious infections, such as endocarditis (Mylonakis and Calderwood, 2001; Breuer *et al.*, 2004).

### Bioprosthetic Heart Valves

The bioprosthetic valve replacements, such as allografts and glutaraldehyde-fixed xenografts, are associated with a lower risk of hemolysis and thrombosis than the mechanical heart valve (Turina *et al.*, 1993; Vongpatanasin *et al.*, 1996). Patients that have glutaraldehyde-fixed xenograft valves do not require anticoagulation therapy and are thus not at risk of anticoagulation-associated bleeding (Cannegieter *et al.*, 1994). Due to their biomechanical characteristics, however, the durability of a glutaraldehyde-fixed valve is more limited than that of the mechanical valve. The predominant disadvantage of replacement valves made from tissue is a progressive structural deterioration that ultimately results in stenosis and/or regurgitation (Grunkemeier and Rahimtoola, 1990; Jamieson, 1993; Turina *et al.*, 1993; Schoen, 1991, 1995; Vongpatanasin *et al.*, 1996; Schoen and Levy, 1999). Structural valve failure nearly always requires reoperation. Because bioprosthetic valves degrade progressively, the rate of failure is time dependent. Fewer than 1% of porcine aortic valve bioprostheses in adults reveal structural dysfunction within five years of implantation (Bloomfield *et al.*, 1991; Hammermeister *et al.*, 1993; Schoen and Levy, 1999; Ferrans *et al.*, 1987; Cohn *et al.*, 1989; Grunkemeier *et al.*, 1994; Jamieson *et al.*, 1995). However, 20–30% become dysfunctional within 10 years, and more than half fail due to degeneration within 12–15 years

postoperatively (Bloomfield *et al.*, 1991; Hammermeister *et al.*, 1993; Schoen and Levy, 1999; Ferrans *et al.*, 1987; Cohn *et al.*, 1989; Grunkemeier *et al.*, 1994; Jamieson *et al.*, 1995). The danger of structural breakdown is also age dependent, with individuals under the age of 35 — especially children and adolescents — having the highest failure rate. In those under the age of 35, near-uniform failure occurs in the first five years following implantation, but only 10% fail in 10 years for those older than 65 (Cohn *et al.*, 1989; Grunkemeier *et al.*, 1994; Jamieson *et al.*, 1995).

The primary source of bioprosthetic valve dysfunction is structural deterioration of the cuspal tissue (Schoen and Levy, 1984; Blackstone and Kirklin, 1985; Schoen and Hobson, 1985; Ferrans *et al.*, 1987; Schoen, 1987; Cohn *et al.*, 1989; Bloomfield *et al.*, 1991; Hammermeister *et al.*, 1993; Grunkemeier *et al.*, 1994; Jamieson *et al.*, 1995; Vongpatanasin *et al.*, 1996). Two distinct yet possibly synergistic mechanisms are implicated: (1) noncalcific degradation and (2) calcific degradation, which can be summarized as noncalcific mechanical fatigue and cuspal mineralization. Both will eventually cause failure of the connective-tissue matrix of the tissue valve (Schoen and Levy, 1984, 1994; Schoen and Hobson, 1985; Ferrans *et al.*, 1987; Schoen *et al.*, 1987; Turina *et al.*, 1993; Vesely *et al.*, 2001). Calcification occurs when blood plasma calcium binds with residual organic phosphorous of the nonviable, cross-linked cells of the preserved valve (Schoen *et al.*, 1985, 1986; Schoen, 1989). Additional weakening can be caused by proteolytic degradation of the collagenous ECM (Sacks and Schoen, 2002). Damage caused from only mechanical force has been observed in explanted porcine aortic valves and has been linked to elevated levels of ECM MMP enzymatic degrading activity in clinical prostheses (Simionescu *et al.*, 1993). It should be noted that the pattern of *in vivo* structural damage in explanted bioprosthetic valves resembles that found in mechanical *in vitro* models. This suggests that mechanical effects alone are probably highly significant in ECM degradation (Sacks and Schoen, 2002).

A different type of replacement bioprosthetic valve is the cryopreserved homograft valve. This has been shown to have advantages in select patient populations, in particular those that require aortic valve replacement or need congenital heart reconstruction with right-sided conduits (Kirklin *et al.*, 1989; O'Brien *et al.*, 1995). The utilization of the cryopreserved homograft, however, is a form of transplantation and therefore suffers from many transplant-associated problems. These include donor organ scarcity and transmission of infection — it has been documented that cryopreserved homografts can be transmitters of infectious disease (Kirklin *et al.*, 1989; O'Brien *et al.*, 1995; Fedalen *et al.*, 1999; Clark *et al.*, 1997). Despite these disadvantages, cryopreserved homografts are the most biocompatible heart valve replacements and used most often in pediatric cardiothoracic applications (Kirklin *et al.*, 1989; O'Brien *et al.*, 1995; McGiffin and Kirklin, 1995). When used in pediatric

cardiothoracic cases, however, they are significantly limited by their incapacity for growth and structural deterioration. This deterioration decreases their durability in a manner similar to that of their glutaraldehyde-fixed xenograft counterparts (Kirklin *et al.*, 1989, 1993; Cleveland *et al.*, 1992).

## V. APPLICATION OF TISSUE ENGINEERING TOWARD THE CONSTRUCTION OF A REPLACEMENT HEART VALVE

### Tissue-Engineering Theory

The ideal heart valve replacement would be readily available and perfectly biocompatible, have the potential for growth, and be durable (Mayer, 2001; Sapirstein and Smith, 2001). The manufacture of an autologous, tissue-engineered heart valve could potentially be a considerable improvement over the best current technology. An autologous tissue-engineered heart valve would be completely biocompatible, nonhemolytic, and nonthrombogenic. It would be capable of utilizing the natural mechanisms for repair, remodeling, and regeneration and thereby be highly durable. In addition it would possess the potential for growth. Since the cells could be harvested from the patient in need of a valve, immune-mediated rejection would be eliminated. In short, a tissue-engineered heart valve could be the ideal replacement heart valve (Shalak and Fox, 1988; Heineken and Skalak, 1991).

The central paradigm for many tissue-engineering projects is cells + matrix → neotissue (Vacanti *et al.*, 1988; Langer and Vacanti, 1993). Three-dimensional cell culture is the fundamental process underlying most tissue-engineering methodologies. The capability of creating an environment for three-dimensional cell growth and neotissue formation is the primary function of the matrix (Shalak and Fox, 1988; Heineken and Skalak, 1991; Vacanti *et al.*, 1988; Langer and Vacanti, 1993). According to this paradigm, cells are seeded onto a matrix composed of synthetic or natural material. Once seeded, the matrix acts as a three-dimensional scaffold on which proliferating cells assemble ECM *in vitro*. When this process yields a sufficiently stable construct, the construct can be implanted *in vivo* (Rabkin-Aikawa *et al.*, 2005) in the desired anatomic location, where further reorganization may happen, thus forming the normal architecture of the tissue. The entire sequence, from *in vitro* seeding to *in vivo* implantation, can be summarized as (1) cell proliferation, sorting, and differentiation; (2) ECM production; (3) degradation of the scaffold; (4) remodeling; and (5) growth of the tissue (Rabkin-Aikawa *et al.*, 2005).

In theory, the principles of tissue engineering can be used to create any tissue type. In actuality, there are several physiologic and biologic limitations when tissue engineering functional neotissue. Some of the more significant factors that currently limit the application of tissue engi-

neering are the inability to control innervation of neotissue, the inability to construct a microvasculature *de novo*, and the challenges surrounding culturing certain cell types (Shalak and Fox, 1988; Heineken and Skalak, 1991; Vacanti *et al.*, 1988; Langer and Vacanti, 1993). Due to these limitations, the most successful tissue-engineering developments have been in neotissues unencumbered by these factors. These neotissues have come principally from tissues that are noninnervated and relatively avascular and whose function is determined primarily by the biomechanical properties of their three-dimensional structure and extracellular matrix (Shalak and Fox, 1988; Heineken and Skalak, 1991; Vacanti *et al.*, 1988; Langer and Vacanti, 1993). Accordingly, the semilunar heart valve is nearly an ideal candidate for tissue engineering (Mayer, 2001; Sapirostein and Smith, 2001).

### Tissue-Engineering Theory Applied to Heart Valves

The semilunar heart valve is not completely avascular, and nutrients and oxygen are supplied via two complementary pathways. The thickest section of the valve is vascularized for transport of oxygen and nutrients (Weind *et al.*, 2001). For the greater portion of the semilunar valve, however, vascularization is unnecessary because oxygen can simply diffuse through both the fibrosa and ventricularis surfaces, given that both surfaces are exposed to blood (Weind *et al.*, 2001). For this reason, it is conceivable that a tissue-engineered semilunar valve may not require development of microvascular circulation (Schoen and Levy, 1999; Mayer, 2001; Sapirostein and Smith, 2001; Weind *et al.*, 2001). Another advantage of tissue engineering a semilunar heart valve is its composition of easily cultured cells. This is a critical characteristic because it allows for the *in vitro* isolation and *in vitro* expansion of autologous cells. Another critical feature enabling the development of a tissue-engineered heart valve is the fact that valve function can be readily studied using well-established techniques, such as Doppler ultrasonography and arteriography (Mayer, 2001; Sapirostein and Smith, 2001). The pathophysiology of valvular dysfunction has also been expansively researched at a variety of levels using molecular, biochemical, and histological analysis (Schoen and Levy, 1999; Schoen, 1987). This analysis can then be used to evaluate the performance of the tissue-engineered heart valve, thus allowing for a prompt appraisal of the tissue-engineered valves in comparison with native valves (Shalak and Fox, 1988; Heineken and Skalak, 1991).

The blueprint for the tissue-engineered heart valve has evolved from a large body of research in bioprosthetic valves, diseased heart valves, and other tissue valve substitutes. Although these investigations were largely clinical, they have identified useful markers of cell function, matrix physiology, and matrix structure. This was summarized by Rabkin-Aikawa and others in five key concepts of functionally

adaptive valvular remodeling/regeneration as follows (Rabkin-Aikawa *et al.*, 2005):

- (1) *The highly specialized arrangement of collagen and other ECM components (particularly elastin and proteoglycans) enables normal heart valve function and is the principal determinant of the durability of heart valves.*
- (2) *Structural deterioration of native and substitute valves is ultimately mediated by chemical and mechanical damage to collagen.*
- (3) *The quality of valvular ECM depends on valvular interstitial cell viability, function and ability to adapt to different environments.*
- (4) *Cell viability in nearly all current bioprosthetic tissue valve substitutes is compromised or completely eliminated during processing; thus, ECM damage, which occurs during valve function following implantation of current bioprosthetic valves, cannot be repaired.*
- (5) *The long-term success of a tissue-engineered valve replacement will, therefore, depend on the ability of its living cellular components to assume normal function, with the capacity to repair structural injury, remodel the ECM, and potentially grow.*

While there is substantial ongoing work to improve valve bioprostheses incrementally through anticalcification pretreatments and design optimization, the advantages of tissue engineering may result in drastically better treatments. This is most evident in pediatric applications, where there is still a large unmet need for very small-size replacement valves. Even with successful surgeries, repeat operations are often required as the patient grows. Tissue engineering with autologous living cells offers the potential to create nonthrombogenic, nonobstructive tissue valve substitutes capable of providing ongoing remodeling and repair and allowing growth in maturing recipients (Rabkin-Aikawa *et al.*, 2005).

### Biomaterials and Scaffolds

Tissue-engineering scaffolds must be biocompatible, biodegradable with safe by-products, and highly porous yet sufficiently mechanically stable to appropriate function (Rabkin-Aikawa *et al.*, 2005). The scaffold must possess properties that promote cell attachment and recapitulate complex tissues. For more complicated applications, the scaffolds may need to be additionally functionalized with bioactive molecules or ligands. Finally, one frequently overlooked requirement is that the scaffolds possess enough robustness to allow for handling by the end user, most usually a surgeon.

Scaffolds can be made from either synthetic or natural materials. Natural biomaterials are usually composed of ECM components: collagen, fibrin, elastin, glycosaminoglycans, and decellularized tissues. Some examples of decellularized tissues used for tissue engineering are decellularized heart valve, pericardium, and arterial wall (Schmidt and Baier, 2000; Hodde, 2002). Synthetic polymers have an advantage in that the raw materials are generally easily available, they can be made reproducibly, their chemistry is predictable, and their properties can be well controlled (Rabkin-Aikawa *et al.*, 2005). The most commonly utilized

synthetic polymers in tissue engineering include the poly  $\alpha$ -hydroxyesters poly(glycolic acid) (PGA), poly(L-lactic acid) (PLLA), and copolymers poly(lactic-co-glycolic acid) (PLGA), and poly(anhydrides) and poly(peptides). Another popular polymer is PHA, or polyhydroxyalkanoate (Rabkin-Aikawa *et al.*, 2005). PHA is a thermoplastic that is biocompatible, resorbable, and flexible and that causes minimal inflammatory response (Williams *et al.*, 1999). In addition, elastic biodegradable polymers are now available as well and may offer additional, unique mechanical advantages (Lendlein and Langer, 2002).

### Natural Matrices

Natural materials were originally picked for intrinsic properties that matched those of native tissue, most often the biomechanical profile. Furthermore, it was not unusual for availability and ease of use to dictate the choice of material. Decellularized small intestinal submucosal (SIS) matrix was one of the first natural materials isolated for use in tissue engineering (Badylak *et al.*, 1989, 1998). Investigators used porcine SIS scaffold as a resorbable matrix to make pulmonary valve leaflet replacements in porcine models (Matheny *et al.*, 2000). Interestingly, the implanted scaffolds seemed to undergo complete resorption (Flanagan and Pandit, 2003).

Another natural scaffold is biodegradable fibrin gels, which are easily made, using the patient's own blood as a source for raw material (Grassl *et al.*, 2002; Neidert *et al.*, 2002). In one experiment, cell-fibrin gel scaffolds were made from human aortic myofibroblasts suspended in a solution of thrombin, fibrinogen, and calcium chloride and allowed to polymerize at 37°C. In order to promote collagen synthesis, the growth media was supplemented with L-ascorbic acid 2-phosphate (Grinnell *et al.*, 1989). This technique was further advanced by developing a molding technique to form a trileaflet heart valve (Jockenhoevel *et al.*, 2001). An adjustable mold made from ventricular and aortic casts was constructed out of aluminum. Ultimately, however, even though the engineered tissue was robust enough for suture, it could not withstand surgical implantation (Flanagan and Pandit, 2003) and suffered from additional drawbacks, such as shrinkage with time. In a similar approach by Ye and colleagues, completely human autogeneic tissue was created without using a supporting scaffold. Briefly, myofibroblasts were cultured in a medium supplemented with L-ascorbic acid 2-phosphate to promote ECM production, forming cell sheets that were then folded into quadrilaminar sheets and mounted on tailored culture frames. These constructs were then cultured for an additional month, after which a multilayer tissue pattern was observed, with active and viable cells surrounded by ECM (Ye *et al.*, 2000).

The majority of the mechanical and tensile strength of the heart valve comes from collagen (Flanagan and Pandit, 2003). For this reason, many investigations have attempted to use collagen as a matrix component. Collagen has been

used as a material for tissue-engineered heart valve scaffolds in applications involving both human and porcine-derived cells (Rothenburger *et al.*, 2001; Taylor *et al.*, 2002). Rothenburger and colleagues utilized a collagen I derived from bovine skin tissue to make a scaffold that was 98% porous. The scaffold was sectioned into disc structures and serially seeded with either porcine or human aortic smooth muscle cells, followed by porcine aortic endothelial cells. After 28 days in culture, the tissue morphology had several layers of cells with newly synthesized ECM components, similar to native tissue. Although collagen scaffolds outperformed other natural materials, they still lacked the sophistication of native structures.

In 1995, a heart valve decellularization process was developed that utilized DNase, RNase, and the detergent Triton X-100 (Wilson *et al.*, 1995). Using this method, cellular components and debris such as nucleic acids, cell membranes, cytoplasmic structures, lipids, and soluble matrix molecules were removed while maintaining the elastin, collagen, and GAG components of the scaffold ECM (Zeltinger *et al.*, 2001). Thus, the sophistication of structure and desired biomechanical properties of the scaffold are theoretically preserved. When these scaffolds were used in a canine model, a four-week follow-up revealed no inflammatory process, partial endothelialization, or partial VIC infiltration at the valvular base (Wilson *et al.*, 1995). The same method for decellularization was used three years later with porcine matrices. These matrices were seeded with human endothelial cells. The resulting construct had a confluent and viable monolayer cell surface, an important feature in reducing thrombogenic risk (Bader *et al.*, 1998). The cross section of the leaflet was largely acellular, and the collagen framework was wavelike, similar to normal tissue. Unfortunately, there were significant interfibrillar spaces, an undesirable characteristic that can affect the biomechanical properties of the tissue. The investigators also had significant difficulties removing cellular remnants, which can act as a nidus for ectopic calcification (Schoen and Hobson, 1985; Valente *et al.*, 1985) or an immune response (Schmidt and Baier, 2000). This work continued in *in vivo* experimentation using a decellularized valve scaffold seeded with autogeneic cells (Steinhoff *et al.*, 2000). Endothelial cells and carotid artery myofibroblasts were added in succession to acellularized pulmonary valve conduits and implanted into ovine models. After one month, the valve leaflets were completely endothelialized. The endothelium remained confluent three months after implantation and had been densely infiltrated by myofibroblasts. There was, however, some indication that subvalvular calcification and inflammation had occurred, along with increased thickening of the valve leaflets (Flanagan and Pandit, 2003).

The commercially available SynerGraft™ valve, manufactured by CryoLife Inc., was based on the decellularized model for tissue engineering (O'Brien *et al.*, 1999). In the SynerGraft™ decellularization process, the cells on the

matrix were lysed in sterile water, while remaining nucleic acid material was enzymatically digested. This was followed by an isotonic washout of several days. Histological evaluation 150 days postimplantation in porcine models revealed healthy leaflets, with local myofibroblasts in growth and no calcific mineralization (Flanagan and Pandit, 2003). This method was developed as an alternative to glutaraldehyde cross-linking to decrease xenograft antigenicity. Early failure of the valve, however, was reported in human trials, as described later in this chapter in the Clinical Applications section (Simon *et al.*, 2003).

As of yet, it is unclear as to what the ideal decellularizing agent for heart valves should be (Flanagan and Pandit, 2003). In a recent evaluation, Triton X-100, sodium dodecyl sulphate (SDS), sodium deoxycholate, MEGA 10, TnBP, CHAPS, and Tween 20 were compared for efficacy. The results revealed that only SDS (0.03–1%) or sodium deoxycholate (0.5–2%) resulted in complete decellularization after 24 hours (Booth *et al.*, 2002). It is possible, however, that any of these agents can have toxic side effects if even trace amounts are left in the scaffold.

### Synthetic Matrices

A number of biodegradable polymers have been explored for use as scaffolds. Biodegradable polymers have the advantage of offering a more biocompatible template on which cells can grow (Flanagan and Pandit, 2003). Proponents of the synthetic matrix believe that using biodegradable polymers can decrease biocompatibility/foreign-body complications. Additionally, they point out that customized polymers can be engineered to exact specifications in a reproducible manner.

Initial work focused on polymers composed of polyglycolic and polylactic acid (Shinoka *et al.*, 1995, 1996, 1997, 1998; Breuer *et al.*, 1996; Zund *et al.*, 1997; Bader *et al.*, 1998). These “off the shelf” polymers were chosen because they are biodegradable, biocompatible, well characterized, and already FDA approved for human use. Furthermore, cells readily attach to and grow on these polymers. The matrices for the heart valves were woven from PLGA microfibers and then layered between two nonwoven PGA mesh sheets. These scaffolds were then serially seeded with arterial myofibroblasts and arterial endothelial cells. Following the seeding, the constructs were transplanted into the pulmonary position as a single leaflet in sheep. The seeded cells were visible in the structure six weeks after implantation, and a postmortem evaluation revealed a native tissuelike architecture (Shinoka *et al.*, 1996). Furthermore, there was positive confirmation of elastin and collagen production in the leaflets (Shinoka *et al.*, 1996). The biomechanical profile of the construct, however, differs considerably from that of the native heart valve. Tissue-engineered heart valves using polyglycolic acid and polylactic acid copolymer-based matrices are thicker, stiffer, and less pliable than native valves.

Following this early work, Stock and collaborators evaluated the more flexible synthetic polymer polyhydroxyoctanoate (PHO) as a material for matrix construction (Stock *et al.*, 2000). The conduit design consisted of a layer of 240- $\mu$ m-thick PHO film inserted between two layers of 1-mm-thick nonwoven PGA felt. Sutured to this conduit were leaflets composed of a monolayer of 120- $\mu$ m-thick porous PHO. Postimplantation examination revealed a uniformly organized tissue with large amounts of collagen and proteoglycans but no elastin. In a different study, a porous PHO scaffold was molded into a trileaflet valved conduit by thermal processing. The resulting scaffold was subsequently seeded with ovine carotid jugular vein endothelial cells and arterial myofibroblasts (Sodian *et al.*, 2000). The constructs were surgically implanted into the pulmonary position of a sheep and harvested after 1–17 weeks. All of the valve constructs opened and closed in harmony and showed an increase in inner length and diameter. Whether this was caused by actual tissue growth or simple construct dilatation was indeterminable. Scanning electron microscopy revealed a smooth leaflet surface; however, histological evaluation did not confirm a confluent endothelium, necessary for long-term stability of the construct. There was some GAG and collagen formation, but no elastin was present.

It was concluded that the hydrolytical stability of PHO made it an undesirable choice of polymer. In addition to being insufficiently replaced by neotissue, the extended scaffold lifetime could increase the potential for unwanted host–tissue reactions, and, in fact, all valve constructs demonstrated some degree of mild stenosis and regurgitation as well as inflammatory responses (Stock *et al.*, 2000; Flanagan and Pandit, 2003).

Hoerstrup and colleagues introduced a unique composite matrix made from PGA coated with a thin layer of poly-4-hydroxybutyrate (P4HB). P4HB is a flexible, thermoplastic polymer that degrades more rapidly than PHO (Hoerstrup *et al.*, 2000; Martin and Williams, 2003). This polymer was used to weld trileaflet heart valve scaffolds under heat. Endothelial cells and myofibroblasts from lamb carotid artery were seeded onto the matrix and then placed in a bioreactor for two weeks (Hoerstrup *et al.*, 2000). The constructs were then implanted into the same animal of cell harvest, where they stayed for as long as five months. Exposure to the bioreactor was shown to induce a more structured internal architecture, increase ECM synthesis, and improve the construct’s mechanical properties versus static controls. The leaflets revealed a layered architecture after four and five months, with a spongy layer comprising GAGs and elastin on the inflow surface and a largely fibrous layer composed mostly of collagen on the outflow surface. However, moderate regurgitation was noted at five months, with only partial endothelialization on the surface of the leaflet.

While it is unclear whether a synthetic or natural matrix type will be of most use in tissue engineering a heart valve,

the scaffold design will be crucial for successful development of a tissue-engineered valve.

### The Search for Appropriate Cell Sources

The ideal cell source for tissue-engineered heart valves is a subject of intense investigation. The use of autologous cells as opposed to allograft or xenograft tissue has the advantage of avoiding an immunological response that could lead to rejection (Shinoka *et al.*, 1995, 1996, 1997, 1998; Breuer *et al.*, 1996; Zund *et al.*, 1997; Bader *et al.*, 1998; Stock and Mayer, 1999). In the earliest attempt to tissue engineer a heart valve, by Shinoka and others, valve leaflets were constructed and implanted in an ovine model by seeding cells from autogeneic and allogeneic sources onto a biodegradable polymeric scaffold (Shinoka *et al.*, 1995). As expected, the autologous structures provoked less of an inflammatory response and rejection in the host, leading them to perform better and fail less often than the allogeneic structures.

Based on this finding, the logical choice of cell source for creating a tissue-engineered heart valve would be VICs and VECs harvested from the patient's own heart valve leaflets, eliminating the risk of rejection while theoretically capturing the requisite phenotypic profile. This proposal was investigated in an ovine model, using tissue from a valve biopsy as a VIC cell supply (Maish *et al.*, 2003). An immediate concern in this process is the potential for wounding the valve. It did not appear, however, that the biopsy itself damaged leaflet function. Any negative long-term effects due to the biopsy, however, were indeterminable, for follow-up studies were never performed. One potential drawback of this approach is that for human patients, it is doubtful that a sufficient number of cells could be isolated and then cultured from the small portion of tissue resected in biopsy. Furthermore, the ease of culturing cells decreases with the patient's age, decreasing the utility of this approach in older patients. Additionally, patients requiring valve replacement often have diseased VECs and VICs, making them less than ideal as a basis for tissue engineering a replacement valve. Thus, the risks associated with valve biopsy are probably too great to make this a viable technique in human trials (Flanagan and Pandit, 2003).

Arterial cells were also briefly explored but ultimately rejected due to the requirement of sacrificing intact tissue and the potential for injury (Hoerstrup *et al.*, 2000; Sodian *et al.*, 2000; Stock *et al.*, 2000; Flanagan and Pandit, 2003). In search of a more practical source, Shinoka and colleagues compared arterial myofibroblasts to dermal fibroblasts as cell sources for a tissue-engineered heart valve (Shinoka *et al.*, 1997). The leaflets arising from dermal fibroblasts were more contracted, thicker, and less organized than leaflets arising from arterial myofibroblasts. Based on these findings it was hypothesized that mesodermal cells, such as arterial myofibroblasts, provide greater phenotypic specialization than ectodermally derived skin fibroblasts. In theory,

this makes the mesodermal cell type more appropriate for the manufacture of a tissue-engineered heart valve.

Myofibroblasts derived from human saphenous vein represent a more realistic source for clinical applications of tissue-engineered heart valves because, unlike arterial cells, they can be harvested without the risk of limb ischemia (Schnell *et al.*, 2001; Flanagan and Pandit, 2003). When cultured on polyurethane matrices, myofibroblasts were shown to be confluent and viable six weeks later. Moreover, in comparison with neotissue derived from aortic myofibroblasts, mechanical stability and collagen production were found to be higher in the saphenous vein-derived structure.

Less damaging cell sources from other tissues have also been evaluated. In 2002 a report demonstrated the feasibility of using autologous umbilical cord cells (Kadner *et al.*, 2002). The cells isolated were a mixed population derived from umbilical cord artery, vein, and the surrounding Wharton's jelly. These cells exhibited myofibroblast-like differentiation, including expression of vimentin, alpha smooth muscle actin, and deposition of collagen type I and collagen type III. Most importantly, they successfully adhered to matrices and formed layered tissuelike architecture similar to matrices seeded with vascular cells (Hoerstrup *et al.*, 2000; Flanagan and Pandit, 2003). Unfortunately, elastin was not successfully produced and only low levels of GAG were found. More work is needed in characterization of the mixed cell population before the suitability of this source can be evaluated. Similarly, mesenchymal stem cells have shown promise for tissue-engineered heart valves, with their ability to differentiate. They can develop into a variety of connective tissues, including cartilage, bone, muscle, and fat, as well as easy collection via simple bone marrow puncture, making these cells an attractive possibility (Pittenger *et al.*, 1999; Caplan and Bruder, 2001).

In a separate experiment, human bone marrow stromal cells were collected by bone marrow puncture and evaluated as a possible cell source (Hoerstrup *et al.*, 2002; Kadner *et al.*, 2002). Like umbilical cord cells, they were shown to undergo myofibroblast-like differentiation, expressing alpha smooth muscle actin and vimentin, and to produce collagen type I and collagen type III. When biodegradable polymeric scaffolds were seeded with these cells, the construct demonstrated advanced tissue development and an ordered internal structure. However, it is unknown if the bone marrow stromal cells differentiate into the desired cell types in the matrix.

The optimal replacement for both VICs and VECs is still being sought. However, given the remarkable differentiation potential of embryonic and adult stem cells, pluripotent cells may become an important feature of tissue-engineered heart valves.

### Cell-Seeding Techniques

The formation of neotissue has not been as simple as providing a scaffold and cells. While relying on cell growth

into unseeded matrices has been undependable, active cell seeding by an assortment of techniques has yielded some success (Shinoka *et al.*, 1995, 1996, 1997, 1998; Breuer *et al.*, 1996; Zund *et al.*, 1997; Bader *et al.*, 1998; Gloeckner *et al.*, 1999; Mitka, 2000; Stock *et al.*, 2001; Rabkin *et al.*, 2002; Sutherland *et al.*, 2002; Engelmayer *et al.*, 2003; Nasser *et al.*, 2003). Cell attachment is a crucial step in initiating cell growth and neotissue development. The majority of synthetic and natural scaffolds initially used for tissue engineering were selected for their biocompatibility, with little knowledge of how cells and tissues attached and grew on these materials. The scaffolds were made more porous in secondary matrix processing, such as salt leaching, to enhance the surface area for cell attachment, increase cell-cell interactions, and enable neotissue ingrowth. More advanced methods sought to augment cell attachment by coating the matrix prior to seeding with a variety of cell adhesion molecules, such as laminin (Shinoka *et al.*, 1995, 1996, 1997, 1998; Breuer *et al.*, 1996; Zund *et al.*, 1997; Bader *et al.*, 1998; Teebken *et al.*, 2000).

It also turns out that the actual approach to cell seeding plays a role in how the cells interact with the matrix — the difference between dynamic and static cell seeding is now well established (Sutherland *et al.*, 2002; Nasser *et al.*, 2003). The traditional approach to polymer scaffold seeding employed established static cell culture techniques. Briefly, a concentrated suspension of cells is pipetted onto collagen-coated polymer matrices and allowed to incubate for a variable time period, during which cell adhesion occurs. In dynamic cell seeding, either the medium or both the medium and the scaffold are in continuous motion throughout the incubation period (Sutherland *et al.*, 2002; Nasser *et al.*, 2003). Nasser found that dynamic cell seeding onto tissue-engineering matrices increased cellular adhesion, seeding density alignment in the direction of flow, and cell infiltration (Sutherland *et al.*, 2002; Nasser *et al.*, 2003). Obviously, many variables can be tuned in such a system, including the use of pure versus mixed cell populations, single-step versus sequential seeding of different cells, and the introduction of intervals (Zund *et al.*, 1999; Ye *et al.*, 2000). Various permutations of these methods are being systematically evaluated in an effort to optimize cell seeding (Gloeckner *et al.*, 1999; Pittenger *et al.*, 1999; Mitka, 2000; Guleserian *et al.*, 2001; Kaushal *et al.*, 2001; Stock *et al.*, 2001; Hoerstrup *et al.*, 2002; Kadner *et al.*, 2002; Rabkin *et al.*, 2002; Sutherland *et al.*, 2002; Engelmayer *et al.*, 2003; Nasser *et al.*, 2003; Perry *et al.*, 2003).

Uniform, adequate, and reproducible cell seeding of both synthetic polymeric and natural scaffolds remains a challenge in tissue engineering. Optimization of rapid seeding techniques will be critical in the effort to tissue engineer a heart valve, for it hastens the proliferation and subsequent differentiation of cells, maximizes the use of donor cells, provides a uniform distribution of cells, and decreases the time in culture (Vunjak-Novakovic *et al.*,

1998). Technical advances in the alteration of matrix surfaces to enhance cell adhesion and function will be needed for short-term *ex vivo* culture of tissues prior to implantation (Flanagan and Pandit, 2003).

### Neotissue Development in the Tissue-Engineered Heart Valve

Upon formation of the cell-scaffold construct, neotissue begins its development. This process, however, is poorly understood and is controlled by many factors. In some characteristics it appears to be a recapitulation of ontogeny, while in others it appears to operate under the mechanisms of tissue repair. In fact, it is most likely a unique process governed by its own set of laws. The cell type implanted and their environment determine the type of tissue that ultimately develops from the cell-scaffold complex (Shalak and Fox, 1988; Heineken and Skalak, 1991; Langer and Vacanti, 1993).

The environment of the growing construct will influence the extracellular matrix and histological structure formed. Scientists have approached this phenomenon from two perspectives. The first is a “black box” approach, where the scaffold is used as a cell delivery device and implanted *in vivo* shortly after cell attachment has taken place (Vacanti *et al.*, 1988; Langer and Vacanti, 1993). The cell-matrix construct is surgically implanted *in vivo* into the environment in which it is expected to function, the justification for this method being that appropriate environmental signals for tissue repair and remodeling are intrinsically present in the *in vivo* milieu (Vacanti *et al.*, 1988; Langer and Vacanti, 1993). In addition, biomechanical forces of the environment provide important stimuli that influence the formation of extracellular matrix and determine the biomechanical properties of the growing neotissue. The assumption underlying this approach is that the cell-scaffold construct possesses the necessary mechanical physicality to provide temporary function until neotissue develops (Vacanti *et al.*, 1988; Langer and Vacanti, 1993).

In a second approach an instrument called a bioreactor is used. A bioreactor is a biomimetic system used for *in vitro* neotissue development. It is used to condition or stimulate the cell-scaffold construct *in vitro* to improve cell attachment, change cellular orientation, and increase the production of extracellular matrix proteins such as collagen and elastin. The bioreactor can also be utilized to adjust the biomechanical properties of the neotissue, which is of special interest in the development of a tissue-engineered heart valve (Gloeckner *et al.*, 1999; Niklason *et al.*, 1999; Hoerstrup *et al.*, 2000; Sodian *et al.*, 2001, 2002a; Jochenhoevel *et al.*, 2002; Engelmayer *et al.*, 2003; Mol *et al.*, 2003). One type of bioreactor used in tissue engineering a heart valve is the pulse duplicator. This pulsatile bioreactor supplies physiological flow and pressure to the developing tissue-engineered heart valve and promotes both the modulation of cellular function and the development of

mechanical strength (Niklason *et al.*, 1999; Hoerstrup *et al.*, 2000; Sodian *et al.*, 2001, 2002a). A bioreactor capable of inducing laminar flow has also been employed and shown to modulate tissue development and extracellular matrix formation. Other versions of bioreactors for tissue engineering the heart valves include bioreactors that can provide increasing dynamic flexural strain or cyclic strain (Engelmayr *et al.*, 2003; Mol *et al.*, 2003). The mechanical straining can induce more pronounced and organized tissue formation. Neotissue made in this way possesses superior mechanical properties over unstrained controls and results in heart valve cusps that are considerably less stiff than static controls (Gloeckner *et al.*, 1999; Sodian *et al.*, 2002a; Engelmayr *et al.*, 2003; Mol *et al.*, 2003).

Tissue-engineered heart valves have been evaluated physiologically, biochemically, histologically, molecularly, biomechanically, and morphologically. In each analysis the tissue-engineered valve was compared with the native valve (Shinoka *et al.*, 1995, 1996, 1997, 1998; Breuer *et al.*, 1996; Zund *et al.*, 1997; Bader *et al.*, 1998). These data could then be examined to identify weaknesses in the tissue-engineered heart valve. This information could then be used for the rational design of an improved tissue-engineered heart valve. The use of feedback of this type is an essential strategy in any biomedical engineering project and will play an important part in tissue engineering a heart valve. For example, insufficiencies in the biomechanical profile of tissue-engineered cardiovascular tissues led to the incorporation of polyhydroxyalkanoate as a polymer for the matrix, and structural weaknesses of the cell-scaffold construct compared with the native valve led to the development of bioreactors (Gloeckner *et al.*, 1999; Niklason *et al.*, 1999; Hoerstrup *et al.*, 2000; Sodian *et al.*, 2001, 2002a; Jochenhoevel *et al.*, 2002; Engelmayr *et al.*, 2003; Mol *et al.*, 2003).

### Clinical Applications of the Tissue-Engineered Heart Valve

Clinical application of the tissue-engineered heart valve has yielded mixed results. Dohmen *et al.* (2002) reported the first success in using a tissue-engineered heart valve. A decellularized cryo-preserved pulmonary homograft was seeded with autologous vascular endothelial cells isolated from a segment of forearm vein. The tissue-engineered valve was used in a 43-year-old patient to reconstruct the right ventricular outflow tract. One year after implantation, the tissue-engineered heart valve demonstrated effectively normal function, with trivial central regurgitation, which had been present since the beginning, no visible calcifications, and smoothly moving leaflets (Dohmen *et al.*, 2002).

Unfortunately, there have been unsuccessful cases as well. Simon *et al.* (2003) reported the use of the Synergraft™ decellularized porcine valve in four children. These decellularized valves had not been seeded with cells or condi-

tioned in a bioreactor before implantation as a simple decellularized scaffold. Three of the four children died from valvular complications, while the fourth had the valve removed. Pathological evaluation revealed a fibrous sheath covering the valves. In addition, a severe inflammatory response was visible, with no signs of cellular repopulation or of endothelialization (Simon *et al.*, 2003). These findings highlight the need for further rigorous laboratory investigation of new tissue-engineering technologies before any additional attempt at clinical application.

To date, there have been no clinical reports of synthetic scaffolds being used to fabricate replacement heart valves. Shinoka *et al.*, however, have applied heart valve tissue-engineering techniques to construct autologous vascular grafts and patches for use as venous conduits in over 40 children with varying forms of congenital heart disease. The synthetic matrix used to create the neotissue was composed of polyglycolic acid and  $\epsilon$ -caprolactone copolymers reinforced with poly-L-lactide. The scaffolds were either seeded with cells expanded from the saphenous vein or directly seeded with bone marrow or mononuclear bone marrow. The first successful clinical demonstration of this method occurred in May 1999 (Shinoka *et al.*, 1997; Matsumura *et al.*, 2003a). Serial postoperative computerized tomography, angiographic, or magnetic resonance imaging examinations revealed no rupture or dilatation of grafts, and there have been no complications related to the tissue-engineered autografts (Isomatsu *et al.*, 2003; Matsumura *et al.*, 2003a, 2003b; Naito *et al.*, 2003). Although histological evaluation is not possible, calcification has been noted by current imaging studies in these patients (Isomatsu *et al.*, 2003; Matsumura *et al.*, 2003a, 2003b; Naito *et al.*, 2003). Shinoka's work proves that the principles of tissue engineering have the potential for a tremendous clinical contribution. The tissue-engineered vascular conduits appear to have minimal risk of infection, no risk of rejection (autologous cell source), reduced incidence of calcification, and potential for growth (Isomatsu *et al.*, 2003; Matsumura *et al.*, 2003a, 2003b; Naito *et al.*, 2003). All of these potential benefits would be possible in a tissue-engineered heart valve as well.

Despite the excellent results of Shinoka *et al.*, and Dohmen *et al.*, the clinical translation of cardiovascular tissue engineering is premature by U.S. standards. The preclinical experimentation needed to provide justification for clinical FDA investigations of tissue-engineered products is in its infancy. The rapid progress of cardiovascular tissue-engineering research has outpaced the regulatory agencies ability to develop governing policies of product development (Mayer *et al.*, 1997; Mayer, 2001). The completion of preclinical studies on which clinical trials can be based is essential for the rational and responsible development of this promising technology. It is time we move beyond feasibility studies and into randomized, controlled preclinical and clinical trials in order to evaluate the true benefits of tissue-engineered heart valves compared to currently used

bioprosthetic and mechanical valves. Investigation of this type will allow us to identify the current limitations of this technology so that we can direct our research toward improving replacement heart valves.

In terms of basic research, recent studies have provided insight into the processes underlying tissue engineering (Stock *et al.*, 2001; Rabkin *et al.*, 2002). These investigations have begun to reveal the dynamics of the extracellular matrix in terms of production, remodeling, and degradation (Stock *et al.*, 2001; Rabkin *et al.*, 2002). These complex mechanisms require the deposition and accumulation of extracellular proteins as well as remodeling by matrix metalloproteinases and their endogenous tissue inhibitors of metalloproteinases (Stock *et al.*, 2001; Rabkin *et al.*, 2002). The cell phenotype and extracellular matrix in tissue-engineered heart valves developed *in vitro* and implanted *in vivo* are dynamic and reflect the capacity of vital tissue to remodel and potentially grow. As our understanding of this process expands, our capability to direct it will also evolve.

## VI. CONCLUSION

Successful development of a tissue-engineered replacement heart valve may hold the key to better treatment of end-stage valve disease. Although significant progress has been achieved since its inception in the early 1990s, the field is young and many key issues need to be resolved. As of yet, we are still limited by our knowledge of the cell biology and ECM production and maintenance of a normal valve. The identification of an ideal cell source and optimal matrix persists as the point of focus in tissue-engineering strategy. It is possible that a more complete understanding of embryonic and fetal heart valve development may provide insight that eventually enables tissue engineers to build consistently clinically acceptable replacement heart valves *ex vivo* (Flanagan and Pandit, 2003). Other important advances will undoubtedly also be needed to allow for the tissue-engineered heart valve to come to fruition and will require contributions from many different disciplines.

### I. INTRODUCTION

Diabetes is a devastating disease affecting millions of people around the world. Islet transplantation has demonstrated that cell therapy works. Although this technique needs further improvements (amelioration islet isolation and survival, new immunosuppressive regimens, etc.), the “proof of principle” for future cell therapies has been established. However, the lack of sufficient donors, together with the need for immunosuppression, limits clinical applications of these techniques. New sources of insulin-producing cells are needed. The possibilities are xenogenic islets, surrogate beta-cells, adult stem cells from the pancreas and other tissues, and bioengineered embryonic stem cells. Macro- and microislet encapsulation may improve islet survival, avoid rejection, and permit immunosuppressive regimen-free transplantations. This chapter discusses these approaches.

Diabetes mellitus as a devastating metabolic disease affects around 2–5% of the world’s population. While type 1 diabetes mellitus is characterized by autoimmune destruction of islets, it is now well recognized that reduced pancreatic beta-cell mass and insulin secretion failure play a pivotal role in the development and progression of type 2 diabetes mellitus (Roche *et al.*, 2005).

Daily insulin injections are necessary for patient survival, mainly in the case of type 1 diabetes. However, diabetic people very often develop late complications, such

as neuropathy, nephropathy, retinopathy, and cardiovascular disorders, because the insulin injection does not mimic  $\beta$ -cell function exactly. The Diabetes Control and Complications Trial (DCCT, 1993) has demonstrated that intensive insulin therapy restores blood glucose homeostasis and subsequently reduces the appearance of diabetic complications. However, it requires educated and motivated patients; long-term follow-up of patients resulted in no clear differences. As a matter of fact, in both type 1 and type 2 diabetes mellitus, impaired blood glucose due to lack or death of  $\beta$ -cells is a common feature; thus, the best perspective for its treatment is beta-cell replacement.

Pancreas transplantation provides good glycemic control and insulin independence, together with an improvement in diabetic complications (Ryan *et al.*, 2006), but it has the associated morbidity of major surgery. Unfortunately, it requires long-term immunosuppression, with its attendant risks. Simultaneous pancreas and kidney transplantation is a worthwhile option to employ when renal transplantation is needed (Ryan *et al.*, 2006).

Clinical islet transplantation trials have been established as proof for beta-cell replacement therapy. Injection of islets isolated from cadaveric organ donor pancreata into the portal vein of type 1 diabetic patients results in insulin independence (Ryan *et al.*, 2005). However, this procedure most often requires the use of islets from more

than one donor, and preserved graft function is based on the use of immunosuppressive medication, which has to counteract both immunorejection and recurrent beta-cell autoimmunity.

Lack of donors, the low yield of islet isolation procedures, and the need for immunosuppression are the most important caveats for future applications of cell therapy for diabetic patients.

## II. ISLET TRANSPLANTATION

Islet transplantation from cadaveric donors has been shown to improve the quality of life of severe diabetic patients. The Edmonton protocol (Shapiro *et al.*, 2000) reported that insulin independence can be reached in type 1 diabetes subjects. The success was attributed mainly to two aspects: (1) the application of a steroid-free new immunosuppressive regime and (2) subsequent transplantation of freshly prepared islets from two or more donors (Shapiro *et al.*, 2000). Five-year follow-up reported that 80% of transplanted patients are C-peptide positive, but only 5–10% maintained insulin independence (Ryan *et al.*, 2005). The side effects of immunosuppressant drugs (mostly diabetogenic), together with recurrent autoimmune attacks, may explain the limited success. In order to achieve successful cell therapies, efficient islet isolation procedures, less toxic immunosuppressive regimes, and the exploration of new places for transplant have to be developed.

### Islet Isolation and Survival

One of the bottlenecks in pancreatic islet transplantation is reaching a high number of functional engrafted islets. It is estimated that only 15–30% of the allogeneic implanted islets are functional, thus forcing the use of two to three subsequent donors to achieve insulin independence. Islet isolation using the semiautomatic Ricordi method remains, with slight modifications, the best method for obtaining high amounts of viable islets.

The yield from islet isolation depends basically on the donor and processing parameters. Several studies have concluded that the islets from normal, overweight, and obese nondiabetic cadaver donors are also suitable (I. Matsumoto *et al.*, 2004). In addition, islets from donors with a low body-mass index non-heart-beating were used successfully in an islet transplantation (Goto *et al.*, 2005). Unfortunately, brain-dead donors promote a rapid anti-inflammatory reaction that predisposes the islets to a subsequent immunologic reaction in the recipient after transplantation (Takada *et al.*, 2004). Limited experience with islets from living donors (S. Matsumoto *et al.*, 2005) suggests better results. Islet transplant from a single donor is possible and results in more uniform islet preparation and makes possible a lower level immunosuppression therapy by searching for a compatible recipient (B. W. Lee *et al.*, 2005).

The Ricordi method may be summarized as follows: organ extraction and transport, perfusion, digestion, and

purification of islets. The maintenance of isolated islets prior to transplant and increasing islet engraftment may be instrumental to increasing the chance of success. *Organ extraction and transport* has requirements similar to those for pancreas transplantation. The use of a two-layer method (perfluorocarbon/University of Wisconsin solution) has been seen to increase the yield and quality of isolated islets (Hering *et al.*, 2004; Papas *et al.*, 2005). However, Papas *et al.* recently have shown that the two-layer method can ameliorate oxygenation in only around 15% of the pancreas (Papas *et al.*, 2005). Preservation solutions, such as M-Kyoto solution, containing trehalose as a cytoprotector and ulinistatin as a trypsin inhibitor improve islet quality significantly as compared to University of Wisconsin solution in the two-layer method (Noguchi *et al.*, 2006). In addition, intraductal glutamine administration improves islet yield, because it protects from lipoperoxidation and apoptosis (Avila *et al.*, 2005).

During *perfusion and digestion* it is necessary to optimize enzymatic digestion by means of liberase H1 and to preserve islet integrity. Excess exposure to enzyme can produce islet fragmentation, decreased insulin secretory ability, and apoptosis (Balamurugan *et al.*, 2005). On the other hand, the automatic method in the Ricordi chamber results in a strong mechanical shaking.

The difference in density between the islets and the rest of the pancreatic tissues allows for *islet purification* by means of separation on continuous density-gradient systems, using the COBE 2991 cell separator. The issues in the purification step are related to the purity and efficiency of the continuous gradient systems. Iodixanol gradients have clear advantages over other gradient systems. When purity is high, the islet fraction is small, whereas a great number of islets may be found in less pure fractionation methods. Recently the additional step named *rescue gradient purification* (RGP) has been described; islets recovered from these fractions were equivalent to islets obtained in a high-purity fraction (Ichii *et al.*, 2005).

With regard to *islet maintenance*, the possibility of increasing viability via subsequent islet culture is being explored by many groups, for example, coculturing islets with Sertoli cells (Teng *et al.*, 2005) as well as with small intestinal submucosa (Tian *et al.*, 2005), the protective effect of L-glutamine and nitric oxide on the islet culture (Tejedo *et al.*, 2004; Brandhorst *et al.*, 2005) has also been described.

Furthermore, in recent years, several experimental strategies have been developed to enhance *islet engraftment*. For instance, antioxidant therapy with nicotinamide (Moberg *et al.*, 2003) as well as sulforaphane (Solowiej *et al.*, 2006), vitamin D<sub>3</sub> (Riachy *et al.*, 2006), 17 beta-estradiol (Eckhoff *et al.*, 2003), pentoxifylline (Juang *et al.*, 2000), caspase inhibitors (Brandhorst *et al.*, 2003), or cholesterol-lowering agents such as simvastatin (Contreras *et al.*, 2002) have all demonstrated a positive impact in the preclinical setting and suggest a potential role in future clinical trials designed to improve islet engraftment. Recently it has been

shown that after intraportal islet transplant, a lipotoxic destruction of islets is induced by hepatic lipids, an effect that can be prevented when the islets have previously been covered with leptin (Unger, 2005).

Additionally, pancreatic islets express tissue factor, the major *in vivo* initiator of coagulation. During clinical islet transplantation, when islets come into direct contact with blood in the portal vein, islet-produced tissue factor triggers a detrimental clotting reaction, referred to as *instant blood-mediated inflammatory reaction* (IBMIR), which is characterized by activation of the coagulation and complement systems, rapid binding and activation of platelets, and infiltration of leukocytes to islets. Together, these effects cause a disruption of islet morphology, islet dysfunction, and death. At present, several forms to inhibit it or to counteract the effects have been proposed (Johansson *et al.*, 2006). Islet surface modification with poly(ethylene glycol) (PEG) was proposed as a strategy to prevent rejection (Contreras *et al.*, 2004; D. Y. Lee *et al.*, 2006). The rationale for this strategy is based on the concept that proteins and enzymes modified with PEG are nonimmunogenic. Incorporation of PEG into the islet surface has been proposed to “camouflage” surface antigens and prevent immunogenic reactions. In addition, PEG has been used successfully to reduce plasma protein adsorption and platelet adhesion to blood vessels and vascular devices because of its low interfacial free energy with water, high surface mobility, and steric stabilization effects. Contreras *et al.* (2004) using xenogenic porcine islets with their camouflaged surface with PEG and additional plus genetic modification to overexpress Bcl-2, and additional surface islet coverage by incorporation of albumin decreasing cytotoxicity mediated by XNA and complement. PEG incorporation onto the islet surface presumably will decrease the binding of platelets on its surface, thereby decreasing IBMIR. The combination of PEG camouflage with immunosuppressive medication would be highly effective in clinical islet transplantation (D. Y. Lee *et al.*, 2006).

## Immunosuppression

Most immunosuppressant agents are diabetogenic. Minimizing these effects while maintaining adequate potency to contend with both allograft rejection and autoimmune recurrence has been instrumental in making islet transplantation a clinical reality. A combination of sirolimus, a low dose of tacrolimus, and daclizumab avoided graft rejection and improved implant survival. Previous reports indicated that the combination of sirolimus and tacrolimus-based trials reported low rates of rejection in liver, kidney, and whole pancreas transplantation (McAlister *et al.*, 2000). Both compounds block T-cell activation. Daclizumab is a monoclonal antibody against IL-2 receptor, allowing the suppression of glucocorticoid administration in patients, which is very harmful to islet cells. The result of this immunosuppressor combination is the prevention of immune response activation and clonal expansion of T-lymphocytes. Sirolimus has

facilitated clinical islet transplant success by providing effective immunosuppression to contend with both auto- and alloimmunity. However, the agent is also responsible for many of the side effects encountered after islet transplantation, including nausea, vomiting, anemia, ovarian cysts, mouth ulcers, diarrhea, optic neuropathy, proteinuria, hypereosinophilic syndrome, parvovirus infection, aspiration pneumonia, severe depression, and hypertension (Hafiz *et al.*, 2005; Ryan *et al.*, 2005). It has also been suggested that sirolimus could still have a detrimental effect on islet engraftment and neovascularization as well as potential detrimental direct toxicity to islets (Hafiz *et al.*, 2005). On balance, however, this agent has proven to be advantageous as compared to former therapies based on steroid and high-dose calcineurin inhibitor. In contrast, combining glucocorticoid-free immunosuppressive strategy with low-dose FK506 tacrolimus and mycophenolate mofetil (MMF) could protect islet grafts in islet transplantation without diabetogenic side effects (Du and Xu, 2006). Pretransplant immunosuppression induction with sirolimus and humanized anti-CD-3 antibody, hOKT3 $\gamma$ 1 (Ala-Ala), in recipients has resulted in engraftment and insulin independence after single-donor islet transplant (Hering *et al.*, 2004).

## Site of Transplantation

The liver is the most commonly used site; islet allografts are infused percutaneously into the portal vein (Shapiro *et al.*, 2000). Potential complications of an infusion into the liver include bleeding, portal venous thrombosis, and portal hypertension (Ryan *et al.*, 2005). Although portal blood pressure is monitored during the procedure and anticoagulant agents are used to prevent clotting, anticoagulation can promote hepatic bleeding at the sites of the percutaneous needle punctures. Furthermore, intrahepatic islets may be exposed to environmental toxins and potentially toxic prescribed medications, such as the immunosuppressive drugs, absorbed from the gastrointestinal tract and delivered into the portal vein. Thus islets transplanted are unable to release glucagon during hypoglycemia. In view of these problems, the use of nonhepatic sites for islet transplantation has been suggested.

The optimal site for transplantation of islets has not yet been defined. The implant site should provide an adequate microenvironment, vascularization, and nutritional support to maximize chances for the best engraftment of cells and to minimize morbidity. Several transplantation sites for islet engraftment have been reported in various experimental animal models, including intraperitoneal, intravenous, intrathecal, intrapancreatic, intrasalivary gland, intracerebral, muscle, spleen, liver via the portal vein, mammary fat pad, anterior eye chamber, omental pouch, testis, and renal capsule (Roche *et al.*, 2005). We used both spleen and kidney capsules as the recipient organ for the bioengineered insulin-positive aggregates (Soria *et al.*, 2000; Leon-Quinto *et al.*, 2004). Transplantation into the spleen is an

experimental technique fast enough to minimize the risk of death in diabetic animals. Although the implanted cells could be traced by means of the expression of a reporter gene (i.e., *h*-galactosidase), graft monitoring could not be followed properly under these conditions because a portion of the cells migrated to the liver and the animal had to be sacrificed (Soria *et al.*, 2001). Kidney capsule appears to be a better place because the graft can easily be obtained via nephrectomy and then analyzed, which allows one to determine *in vivo* differentiation processes and structural changes in the implanted tissue

### III. ALTERNATIVE SOURCES OF ISLET CELLS

Organ procurement from cadaveric donors, even in countries like Spain, which ranks number one in the world in organ donation, will always be a limited source of islets. Search for alternative sources becomes a necessity. Xenogenic islets, bioengineered beta-cells, and directed differentiation of embryonic and adult stem cells could be considered.

#### Xenogenic Islets

Xenogenic sources have been proposed, but they have problems related to immunological and physiological incompatibility, to the identity of insulin as compared to human insulin, and to the risk of zoonotic disease transmission, mainly retrovirus. Porcine islets are the most studied source. They have a control of glucose similar to that of humans, and the insulin has been used for more than 70 years in diabetic humans. Rejection of porcine islets is substantially greater than that of human islets. However, following the development of transgenic humanized pigs lacking xenoantigens, these are more resistant to immune attack (Phelps *et al.*, 2003), and the possibility exists of producing transgenic pigs with individualized matching for recipient HLA types. Zoonotic disease represents, however, a major drawback. Xenogenic islet encapsulation has been explored in detail (Lanza *et al.*, 1999; de Groot *et al.*, 2004; Qi *et al.*, 2004; Schaffellner *et al.*, 2005). *In vitro* experiments suggest that encapsulation is an effective barrier to diffusion of zoonotic disease (Petersen *et al.*, 2002).

#### Bioengineered $\beta$ -cells

Beta-cell surrogates have to achieve expression, processing, packaging, storing, and secretion of insulin in a glucose-dependent manner (Samson and Chan, 2006). Different cell types have been genetically modified to express GLUT 2, glucokinase, and insulin (Faradji *et al.*, 2001), although the results obtained so far are not satisfactory. Coexpression of GLUT 2 and glucokinase in intermediate lobe pituitary cells causes death by apoptosis due to an increment of cytotoxic effects in the presence of 3 mM of glucose (Faradji *et al.*, 2001). Nevertheless, the principal

limitation to the use of transformed insulin-producing cell lines is the uncontrolled proliferation of these cells.

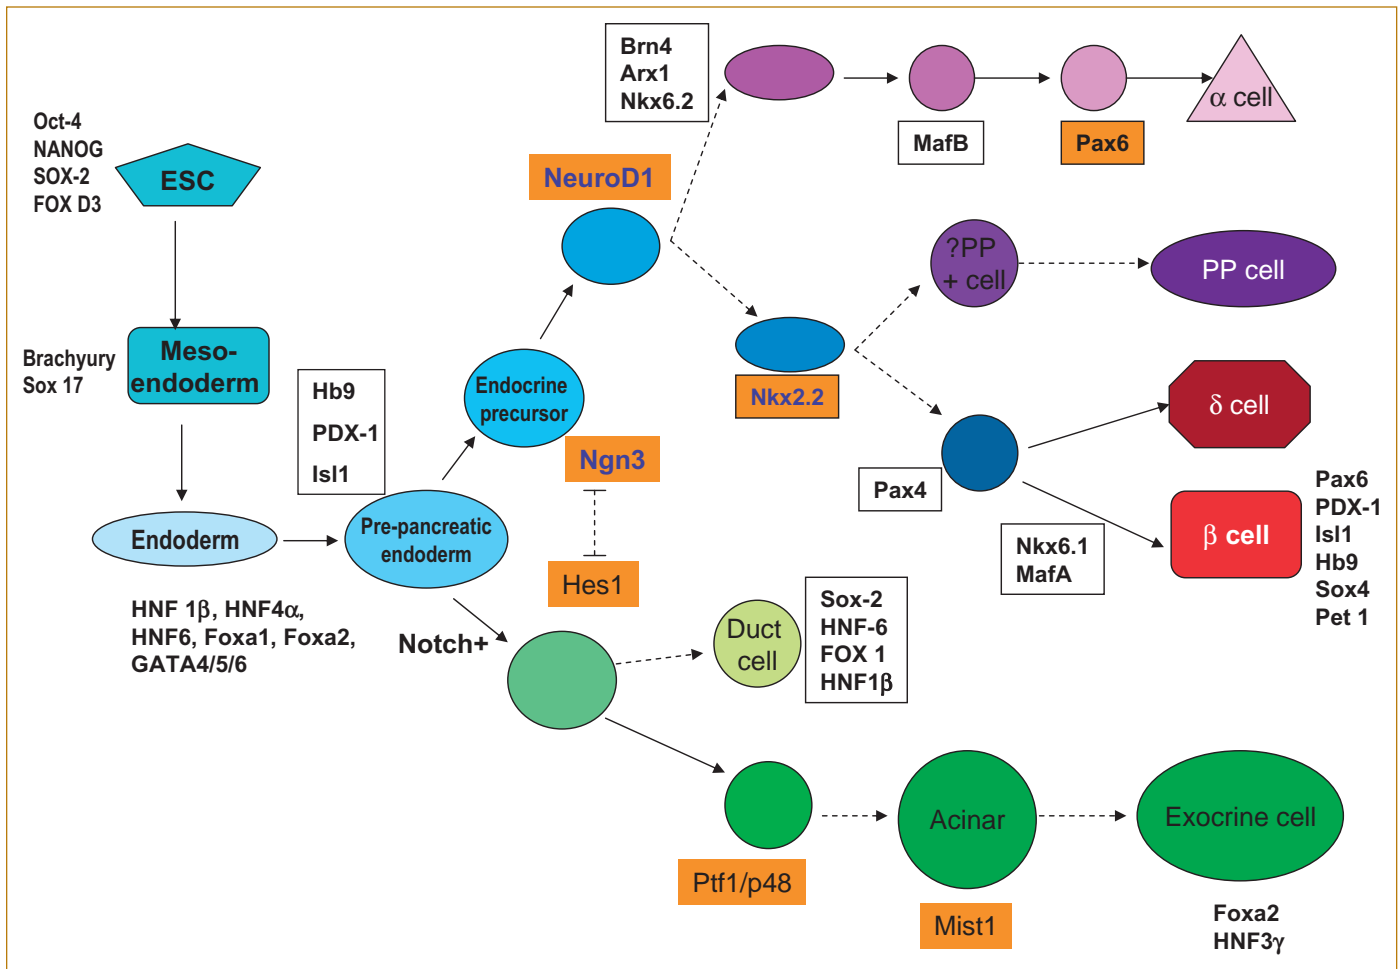

Hepatocytes are good candidates to be used as templates to obtain surrogate beta-cells. Hepatocytes possess similar glucose-sensing machinery to that of beta-cells and express glucokinase and glucose transporter 2 (GLUT2). Rat hepatocytes transfected with PDX1-VP16, a superactive version of PDX1, can be transdifferentiated into insulin-producing cells in the presence of high levels of glucose (Cao *et al.*, 2004). Human liver cells transfected with PDX-1 are able to transdifferentiate into insulin-producing cells in the presence of nicotinamide and epidermal growth factor (Sapir *et al.*, 2005). Hepatocytes transformed with human insulin cDNA express and secrete insulin that is regulated by low glucose and nitric oxide production (Qian *et al.*, 2005). These cells can modulate the hyperglycemia when they are transplanted in diabetic animal models. The expression of PDX1 human fetal liver cells induces the activation of beta-cell genes and has functional beta-cell characteristics. When these cells were cultured in starved-serum conditions in the presence of activin, they differentiated into insulin-producing cells that produce approximately 60% of the insulin content of normal beta-cells and regulate the hyperglycemia in diabetic animal models (Zalzman *et al.*, 2005). Taken together these results suggest that the liver is a potential autologous source of insulin-producing cells.

Another approach has exploited the characteristics of the gut-associated K-cell. This cell possesses a peptide secretory pathway, since one of its functions is to enhance insulin release through secretion of the glucose-dependent insulinotropic polypeptide (GIP). Intestinal mucosal K-cells transfected with the human preproinsulin gene have been injected into mouse embryos. Implanted mice not only produced human insulin within the gut, but also maintained sufficient synthesis and secretory capacity to protect the mice from diabetes following deliberate destruction of the endogenous beta-cell mass (Cheung *et al.*, 2000).

#### Pancreatic Stem Cells

The pancreas is an endoderm-derived organ, consisting of exocrine and endocrine cells. Development of the endocrine cells begins with a common multipotent precursor that is directed along divergent pathways to form the different cell types contained in the islets of Langerhans:  $\alpha$ -cells (glucagon),  $\beta$ -cells (insulin),  $\delta$ -cells (somatostatin), and PP cells (pancreatic polypeptide). This process is dependent on a set of transcription factors (Samson and Chan, 2006).

A cascade of these factors coordinates the stepwise changes in gene expression that guide pluripotent pancreatic progenitor cells along the pathway to mature pancreatic cells (Fig. 41.1). During embryonic development these cells derived from a common stem cell, characterized by the expression of hepatocyte nuclear factor 6 (HFN-6) (Poll *et al.*, 2006) and Pdx-1 transcription factor (Wilding and

**FIG. 41.1.** Hierarchical cascade of transcription factor in the development of pancreatic tissue from embryonic stem cells. Adapted from Samson and Chan (2006).

Gannon, 2004). Pdx-1 leads downstream to Ngn3 factor expression, which is a member of the basic helix-loop-helix (bHLH) family. This factor specifies an endocrine-cell fate (Watada, 2004). Beta2/NeuroD, NeuroD/BETA2 is another basic helix-loop-helix pro-endocrine factor activated by Ngn3 downstream of PDX-1 in the endocrine developmental cascade. Beta2/NeuroD heterodimerizes with ubiquitous bHLH proteins of the E2A family to regulate transcription of the insulin gene and other  $\beta$ -cell-specific genes (Huang *et al.*, 2002). Isl 1 is a LIM homeodomain-family member that controls the differentiation of postmitotic endocrine progenitors. Isl 1 interacts with Beta2 to promote insulin gene transcriptional activation (Peng *et al.*, 2005). The activity of the NK-family member and homeodomain protein Nkx2.2 is necessary for the maturation of  $\beta$ -cells. Nkx2.2 expression is dependent on the NeuroD 1 only in  $\beta$ -cells (Sander *et al.*, 2000; Itkin-Ansari *et al.*, 2005), whereas its distant homolog Nkx6.1 controls their expansion (Sander *et al.*, 2000). The Pax-gene family encodes a group of transcription factors that are key regulators of vertebrate organogenesis, since

they play major roles in embryonic pattern formation, cell proliferation, and cell differentiation. Pax4 is a paired-box homeoprotein whose expression is restricted to the central nervous system and the developing pancreas (Sosa-Pineda, 2004). Thus, Pax4 functions early in the development of islet cells to promote the differentiation of  $\beta$ - and  $\alpha$ -cells. Pax6, also important for  $\beta$ -cell development, regulates the promoters of insulin, glucagon, and somatostatin genes and molecules of adhesion (Sosa-Pineda, 2004).

### Embryonic Stem Cells

Embryonic stem cells (ESC) have self-renewal capacity in defined culture conditions and potential to differentiate into any cellular types present in the developed organism. ESC are derived from the inner mass of blastocyst (Fig. 41.2) and can be induced to differentiate into different lineages *in vitro* by means of the specific differentiation protocols to generate cardiomyocytes, endothelial cells, glial precursors, neurons cells, and oligodendrocytes (Wobus and Boheler, 2005).

**FIG. 41.2.** Derivation of embryonic stem cells from the inner mass of the blastocyst.

Mouse ESC can be induced to differentiate into insulin-producing cells (Soria *et al.*, 2000; Soria *et al.*, 2001). Using a cell-trapping system we have been able to develop methods to obtain insulin-producing cells from embryonic stem cells. Insulin-producing cells correct hyperglycemia when transplanted into diabetic animal models (Soria *et al.*, 2000; Leon-Quinto *et al.*, 2004; Vaca *et al.*, 2006). ESC are transfected with a vector that contains two selection cassettes, one controlling the expression of antibiotic resistance that permits the selection of transfected cells, and another a chimeric gene containing a functional specific promoter driving the expression of a structural gene that codifies for antibiotic resistance allowing the selection of cells that express the selected gene (Fig. 41.3). This method has been shown to work with insulin and Nkx 6.1 promoters (Soria *et al.*, 2000; Leon-Quinto *et al.*, 2004; Vaca *et al.*, 2006).

Recently we published a protocol in which fetal soluble factor from pancreatic buds were used to direct ESC differentiation into insulin-producing cells further selected with a human insulin promoter— $\beta$ geo/PGK-hygro construction (Vaca *et al.*, 2006). Further improvements in the differentiation and selection procedure will result in better results.

Furthermore, expression of some  $\beta$ -cell development transcription factors may promote differentiation of ESC into betalike cells, i.e., Pax-4 constitutive expression (Sosa-Pineda, 2004), Pdx-1 overexpression regulated by a Tet-off regulation system (Miyazaki *et al.*, 2004), or Nkx2.2-transfected ESC (Shiomi *et al.*, 2005). Preliminary results suggest the potential use of human embryonic stem cells to obtain betalike-cells (Brolen *et al.*, 2005).

### Adult Stem Cells

Transdifferentiation of adult cells into insulin-producing cells also provides another exciting opportunity for  $\beta$ -cell expansion (Ruhnke *et al.*, 2005; Seeberger *et al.*, 2006). Recently our group has published the about obtaining betalike-cells from white blood cells by reprogramming blood monocytes in the presence of macrophage colony-stimulating factor and interleukin 3, followed by incubation with epidermal and hepatic growth factor and nicotinamide. These cells showed an *in vitro* glucose-dependent insulin secretion and normalized blood glucose levels in diabetic mice (Ruhnke *et al.*, 2005). While these strategies seem promising, more studies are needed.

**FIG. 41.3.** Protocol for differentiation of ESC into insulin-producing cells. Adapted from Soria *et al.* (2001).

Generation of betalike cells from human adult pancreatic tissues has also been explored, such as development of differentiated islets from pancreatic duct cells and mesenchymal stem cells from human pancreatic ductal epithelium (Gershengorn *et al.*, 2004; Seeberger *et al.*, 2006), human adult pancreatic tissues (Lechner *et al.*, 2005), nonendocrine pancreatic epithelial cells (Hao *et al.*, 2006), and proliferating human islet-derived cells (Ouziel-Yahalom *et al.*, 2006). It is interesting that nonendocrine pancreatic epithelial cells were capable of endocrine differentiation when they were incubated with factors present in human fetal pancreas cells.

The strategy of redifferentiation with proliferating human islet-derived cells includes environmental activation of transcription factors such as Pdx-1, Neuro D, Nkx 2.2, and Nkx 6.1 by betacellulin, a member of the epidermal growth factor family (Ouziel-Yahalom *et al.*, 2006).

## IV. BIOMATERIALS

### Immunological Considerations

Transplanted islets are recognized as antigens by a host, triggering the process of recruiting and activating of immune cells, such as macrophages, fibroblasts, granulocytes, and

lymphocytes. The activated immune cells secrete various cytokines and cytotoxic molecules, which can induce functional and structural damage to islets (Sigrist *et al.*, 2005). In addition, inflammatory cytokines such as interferon- $\gamma$  stimulate the production and release of chemokines by transplanted islets. These chemokines promote the activation of macrophages and have been implicated in a series of biochemical, metabolic, and functional changes, such as increased phagocytosis capacity, chemotaxis, and secretion of chemoattractants, that result in the hampering of islet engraftment (Sigrist *et al.*, 2004). Interleukin (IL)-1 activates T-cells, resulting in the increased production and expression of IL-2 and IL-2 receptor (IL-2R), which are considered the major components of immune rejection. Selective prevention of the IL-2/IL-2R interaction using the IL-2R binding agent prolongs allograft survival. TNF- $\alpha$  increases adhesion of molecules on the grafted tissue, thereby stimulating graft rejection as well as inducing cell death by apoptosis. Recently it has been described that the granzyme B produced by allogenic cytotoxic T-lymphocytes participates actively in the rejection (Sutton *et al.*, 2006). In addition, nitric oxide and reactive oxygen species generated by activated macrophages act as a cytotoxic factor (Chae *et al.*, 2004; Sigrist *et al.*, 2005).

### Encapsulation

Encapsulation of pancreatic islets for transplantation into diabetic patients may solve two major obstacles in clinical applications. (1) Immunoisolation may allow for transplantation of islets in the absence of immunosuppression; (2) it may permit grafting of xenogenic islets, insulin-producing cells differentiated from stem cells, or surrogate beta-cell lines, thereby overcoming the logistical problems associated with the limited supply of human pancreases.

Encapsulation of cells or artificial organs consists of placing them inside bioactive materials (usually polymeric membranes, such as alginate), whose physicochemical properties facilitate free diffusion of nutrients, oxygen, electrolytes, and therapeutic bioactive secretory and cellular waste products produced in their inner while avoiding the intake of proteins of high molecular weight, such as the immunoglobulins, and cells of the immune system (Fig. 41.4). Nevertheless, cytokines and chemokines possess a molecular weight close to insulin, so a molecular filter cutoff will not exclude the cytokines and chemokines responsible for the immune response (Sigrist *et al.*, 2005). Encapsulation has not yet been applied in clinical practice, mainly because survival of encapsulated islet grafts is limited. The principal causes for the failure of microencapsulated islet grafts relate to lack of biocompatibility, limited immunoprotective properties, and hypoxia (de Groot *et al.*, 2004).

Encapsulated allogenic and xenogenic islets differ regarding the specific immunologic response when they are transplanted. Allograft rejection occurs as a result of the

**FIG. 41.4.** Immunoisolation concept and microcapsule models. The islets are being enveloped in alginate-based microcapsules (alginate, poly-lysine, alginate), which permit the free diffusion of glucose, insulin, nutrients, wastes, and chemokines. The microcapsule protects from the immune system reactions and can protect from nitric oxide and reactive oxygen species. The size of the pore retains the xenogeneic virus.

activation of cellular immunity by interactions of host T-cells with the islet graft, as previously described, while humoral immunity, including antibodies and complement proteins, is mostly responsible for the rejection of xenografts. It is important to consider that xenografts are less capable of binding and responding to human cytokines. Immunoisolation may also protect against antigens of allogeneic or xenogeneic cells. Such antigens could be cell surface molecules and cell components, including those released on cell death. Shedding of antigens from encapsulated cells would initiate a molecular tissue response around the implant, which could affect the viability and function of the encapsulated cells. The recognition of antigens through this indirect pathway may lead to the activation of T helper cells, which then secrete cytokines and regulate the cell-mediated immune response and inflammation (Kizilel *et al.*, 2005). Other strategies that complement encapsulation should be explored to avoid the damage that free diffusion molecules such as nitric oxide and free-radical oxygen molecules can cause (Chae *et al.*, 2004).

Islets could be either macro- or microencapsulated. Macroencapsulation can use either extravascular or intravascular devices (Kim *et al.*, 2005; Kizilel *et al.*, 2005). Microencapsulation envelops islets in an alginate-based membrane and other biomaterials (Lanza *et al.*, 1999; Kim *et al.*, 2005).

**Table 41.1.** Advantages and disadvantages of transplantation of unencapsulated, microencapsulated, and macroencapsulated islets (adapted from Emerich *et al.* 1992)

<i>Unencapsulated</i>	<i>Microencapsulation</i>	<i>Macroencapsulation</i>
<b>Advantages</b>		
Anatomical integration between host and transplanted islet	Use of allo- and xenoislets without immunosuppression Thin wall and spherical shape are optimal for cell viability and free diffusion of nutrients and insulin	Use of allo- and xenoislets without immunosuppression Good mechanical stability Good cell viability and free diffusion of nutrients and insulin Retrievable
<b>Disadvantages</b>		
Requires immunosuppression	Mechanically and chemically fragile	Internal characteristics (i.e., diameter) may potentially limit free diffusion of nutrients/insulin and cell viability
Tissue availability limited	Limited retrievability	Need for multiple implants may produce significant tissue displacement/damage
Tissue survival often poor Limited retrievability		

The advantages and disadvantages of both are shown in Table 41.1.

### Macroencapsulation

Macroencapsulation refers to the enveloping of a large mass of islets in a chamber of a perm-selective membrane, forming either an intravascular macrocapsule (connected as a shunt to the systemic circulation) or an extravascular macrocapsule (transplanted subcutaneously or intraperitoneally) (Fig. 41.5). Intravascular macrocapsules are usually perfusion chambers of microporous or nanoporous material that are directly connected to the blood circulation. Extravascular macrocapsules are usually diffusion chambers in the shape of a tube or sphere. The typical dimension of macrocapsules is in the range of 0.5–1.5 mm inner diameter and 1–10 cm length (Kizilel *et al.*, 2005).

Polymers for macroencapsulation are mechanically more stable and the wall capsule generally thicker than those used in microencapsulation. So this technique gives greater long-term stability to the implant. However, the thicker wall and the larger diameter of the capsule can impair diffusion, threatening the viability of the islet and slowing the insulin kinetic release as a result of diffusion limitations of nutrients and oxygen. To guarantee adequate feeding of the cells, the islet density of the macrocapsules is kept quite low and never exceeds 5–10% of the volume fraction. Optimal results have been obtained by immobilization of the islets in a matrix before final macroencapsulation. As a consequence, large devices have to be implanted to provide sufficient masses of insulin-producing islets. These large graft volumes are impractical and cannot be implanted in conventional sites for transplantation of

islets such as the liver, kidney capsule, or spleen. Even the relatively large space in the peritoneal cavity does not suffice for the large volume required for the long-term function of an islet graft in macrocapsules. Also, the relatively large surface-to-volume ratio of the macrocapsules interferes with adequate regulation of the glucose levels, because exchange of glucose and insulin occurs rather slowly. One advantage of the implantation of macrocapsules is the ease of retrieval in case of complications (Kizilel *et al.*, 2005). Macroencapsulated rat islets implanted in the peritoneal cavity of diabetic mice maintained an effective insulin secretory response (Qi *et al.*, 2004).

Bioartificial pancreases should avoid the possibility of contamination with virus from xenogenic islets while allowing insulin and nutrient exchanges. Hydroxymethylated polysulphone macrocapsules display insulin release kinetics very similar to those of free-floating islets and retain retrovirus release (Petersen *et al.*, 2002).

### Vascularization

Postimplantation conditions such as the design of the capsule, the environment at the implantation site, and the development of fibrosis around the construct can produce hypoxia-induced death of islet (Papas *et al.*, 1999). Enhancing the oxygenation of the capsule will increase the number of viable cells within and thus its overall secretory capacity. In this context, neovascularization around the capsule may be beneficial for the overall efficacy of such tissue substitutes *in vivo*. Encapsulated islets promote vascularization after transplantation due to VEGF release (Lembert *et al.*, 2005). A prevascularized site in the intermuscular space may be created by implanting a polyethylene

**FIG. 41.5.** Models of macrocapsules. Extravascular macrocapsule and intravascular macrocapsule.

terephthalate (PET) mesh bag with a collagen sponge and gelatin microspheres containing basic fibroblast growth factor (bFGF), before the implantation of islet macroencapsulates (Balamurugan *et al.*, 2003).

### Biocapsules

Nanoporous biocapsules are bulk and surface micro-machined to present uniform and well-controlled pore sizes as small as 7 nm, tailored surface chemistries, and precise microarchitectures, in order to provide immunoisolating microenvironments for cells. Such a design may overcome some of the limitations associated with conventional encapsulation and delivery technologies, including chemical instabilities, material degradation or fracture, and broad membrane pore sizes (Desai *et al.*, 2004).

### Microencapsulation

Islet microencapsulation was first proposed in 1964 (Chang, 1964) and has been shown to be useful in maintain-

ing glucose homeostasis in rodents, dogs, and primates (Elliot *et al.*, 2005; Kizilel *et al.*, 2005; Calafiore *et al.*, 2006; Dufrane *et al.*, 2006).

Alginate-polylysine-alginate (Fig. 41.4) is most frequently used because it has been found not to interfere with cellular function and to be stable for years in small and large animals as well as in human beings (Lanza *et al.*, 1999; de Groot *et al.*, 2004; Elliot *et al.*, 2005; Calafiore *et al.*, 2006). Alginate is a polysaccharide extracted from seaweed. In solution it has a high viscosity, but in the presence of polyvalent cations, such as  $\text{CaCl}_2$ , it forms gels less insoluble in water. Impurities present in alginate polymers may contribute to the failure of the encapsulated islet implants. Alginates containing higher fractions of  $\alpha$ -L-guluronic acid (G blocks) residues are more biocompatible (i.e., they do not induce a cytokine response from monocytes) than those containing a larger fraction of  $\alpha$ -D-mannuronic acid (M blocks) residues. Omer *et al.* (2005) obtained smaller microcapsules with better stability and biocompatibility using highly purified

alginate containing high G or M blocks with low endotoxin levels and  $\text{BaCl}_2$  as cross-linked agent. In addition, simultaneous incorporation of alginate,  $\text{BaCl}_2$  and human serum albumin improves the biocompatibility and protects adult rat and human islets against xenorejection for long periods after transplantation (Omer *et al.*, 2005). Several other strategies for increasing biocompatibility have been assayed, such as the use of alginate-poly-L-lysine-alginate modified with polyethyleneglycol (Desai *et al.*, 2000), polyacrylates (Isayeva *et al.*, 2003), agarose (Kobayashi *et al.*, 2003), sodium cellulose sulfate (Schaffellner *et al.*, 2005), and the polymerization of acrylamide monomers on islet cells encapsulated in agarose microspheres (Dupuy *et al.*, 1988). Also, surface coating with polyethylene oxide improves the viability of microencapsulated islets by promoting oxygen supply and reduces the absorption of proteins associated with fibrotic reaction (Kim *et al.*, 2005). Despite all these efforts to increase biocompatibility, it has not been possible to eliminate the formation of fibrotic outgrowths.

An encapsulation system that improves strength and mechanical stability has been obtained using a double cross-linked simple physical mixture of sodium alginate (ionically cross-linked) and a polyethylene glycol-acrylate (PEGA) (covalently cross-linked) to form AP capsules, where the porosity and permeability depend on the ratio of alginate to PEGA. Tests *in vitro* have shown that the AP capsules provide a biocompatible and nontoxic environment for islets and are capable of retaining normal functions (Desai *et al.*, 2000).

The immunoprotective properties of the microcapsules are related to the physicochemical characteristics. Polymers containing sulfonic acid or sulfate groups, which have a strong affinity for complement proteins, improve these properties. With xenogenic islets, where the complement reaction is the principal humoral immune reaction, the poly(styrene sulfonic acid) mixed with agarose protects xenogenic islets in mice (Petersen *et al.*, 2002; Lember *et al.*, 2005).

Since all polymers used for immunoisolation are not completely inert, several researchers are now studying the use of condrocytes and their matrix for islet encapsulation, to prevent immunorecognition and destruction of transplanted islets (Pollok *et al.*, 2001).

### Optimal Site for Transplantation

Selecting the optimal transplantation site for microencapsulated islets is an important consideration. Transplantation of microencapsulated xenogenic islets into intraperitoneal sites has been studied. Pig islets encapsu-

lated in an alginate-based matrix survive for over 200 days in chemically diabetic animal models (Omer *et al.*, 2005). However, a high number of encapsulated pig islets and graft failures were also observed in most mice after 42 days of implantation. The variation observed is usually attributed to insufficient biocompatibility of the microcapsule, which causes an accumulation of macrophages and fibroblasts on the microcapsule, provoking necrosis of the islets. Dufrane *et al.* (2006) investigated the impact of implantation sites on the biocompatibility of alginate-encapsulated pig islets in nondiabetic rats. Thirty days after transplantation, explanted capsules from intraperitoneal sites demonstrated a higher degree of broken capsules and capsules with severe cellular overgrowth. On the other hand, capsules removed from subcutaneous and kidney subcapsule sites showed no such damage. They concluded that kidney subcapsular and subcutaneous spaces represent an interesting alternative.

Recently the Calafiore team (University of Perugia, Italy) published their results of pilot phase-1 clinical trials with the human allograft islet microencapsulated in 1.6% sodium alginate and sequentially double-coated with 0.12% and 0.06% poly-L-ornithine and finally with 0.04% sodium alginate. The islet microencapsulates were intraperitoneally (IP) implanted into two selected nonimmunosuppressed patients with type 1 diabetes. Both patients showed a rise in sCPR levels several weeks posttransplant, amelioration of their mean daily blood glucose levels, and a progressive decline in exogenous insulin consumption. GHb also decreased throughout months of posttransplant follow-up. At 60 days posttransplant, an OGTT in patient 1 showed a biphasic C-peptide response, compatible with the presence of differentiated islet  $\beta$ -cells. At 1 year (patient 1) and 6 months (patient 2) of posttransplant follow-up, sCPR was still being detected in these recipients (Calafiore *et al.*, 2006).

On the other hand, cytotoxic molecules produced by activated macrophages such as IL-1 $\beta$ , TNF- $\alpha$ , NO, and reactive oxygen species may also pass through the polymer membrane and damage the transplanted tissue (Chae *et al.*, 2004). The strategies used to protect the islet from these molecules are diverse. As an approach to preventing NO-induced damage, the rat islet and insulinoma cells (RINm5F) microencapsulated in alginate-poly-L-lysine-alginate were coencapsulated with cross-linked hemoglobin (Hb-C)-poly(ethylene glycol). These strategies protect from damage induced by nitric oxide and prevent islet death by hypoxia (Chae *et al.*, 2004).

### I. INTRODUCTION

Diabetes is a significant health problem, affecting an estimated 20.8 million people in the United States alone, with nearly 1.8 million afflicted with type 1 diabetes [<http://diabetes.niddk.nih.gov/dm/pubs/statistics/index.htm#7>]. Type 1 diabetes results from the loss of insulin-producing cell mass (the  $\beta$ -cells of pancreatic islets) due to autoimmune attack. Type 2 diabetes has a more complicated disease etiology and can be the result of not producing enough insulin and/or the body's developing a resistance to insulin. Although initially controlled by diet, exercise, and oral medication, type 2 diabetes often progresses toward insulin dependence. It is estimated that insulin-dependent diabetics (both types 1 and 2) exceed 4 million people in the United States. Although insulin-dependent diabetes (IDD) is considered a chronic disease, even the most vigilant insulin therapy cannot reproduce the precise metabolic control present in the nondiseased state. The poor temporal match between glucose load and insulin activity leads to a number of complications, including increased risk of heart disease, kidney failure, blindness, and amputation due to peripheral nerve damage. Providing more physiological control would alleviate many of the diabetes-related health problems, as suggested by findings from the Diabetes Control and Complications Trial (The Diabetes Control and Complications Trial Research Group, 1997) and its continuation study (DCCT/EDIC NEJM 353(25):2643–53, 2005). Cell-based therapies, which provide continuous regulation

of blood glucose through physiologic secretion of insulin, have the potential to revolutionize diabetes care.

Several directions are being considered for cell-based therapies of IDD, including implantation of immunoprotected allogeneic or xenogeneic islets, of continuous cell lines, or of engineered non- $\beta$ -cells. For allogeneic islet transplantation, a protocol developed by physicians at the University of Edmonton (Shapiro *et al.*, 2001a, 2001b, 2001c, Bigam and Shapiro, 2004) has dramatically improved the survivability of grafts. The protocol uses human islets from cadaveric donors, which are implanted in the liver of carefully selected diabetic recipients via portal vein injection. The success of the Edmonton protocol is attributed to two modifications relative to earlier islet transplantation studies: the use of a higher number of islets and the implementation of a more benign, steroid-free immunosuppressive regimen. However, two barriers prevent the widespread application of this therapy. The first is the limited availability of human tissue, because generally more than one cadaveric donor pancreas is needed for the treatment of a single recipient. The second is the need for life-long immunosuppression, which, even with the more benign protocols, results in long-term side effects to the patients.

A tissue-engineered pancreatic substitute aims to address these limitations by using alternative cell sources, relaxing the cell availability limitation, and by reducing or eliminating the immunosuppressive regimen necessary for survival of the graft. A number of significant challenges are

**FIG. 42.1.** Approaches for bioartificial pancreas development using allo- or xenogeneic cells (A) and autologous cells (B). In (A), islets are procured from pancreatic tissue, or cell lines are thawed from cryostorage and expanded in culture; cells are encapsulated for immunoprotection before they are implanted to achieve a therapeutic effect; encapsulated cells may also be cryopreserved for inventory management and sterility testing. In (B), cells are retrieved surgically from the patient; manipulated *ex vivo* phenotypically and/or genetically in order to express  $\beta$ -cell characteristics, and in particular physiologically responsive insulin secretion; the cells are implanted for a therapeutic effect either by themselves or, preferably, after incorporation in a three-dimensional substitute; some of the cells may be cryopreserved for later use by the same individual. In *in vivo* gene therapy approaches, a transgene for insulin expression is directly introduced into the host and expressed by cells in nonpancreatic tissues.

facing the development of such a substitute, however. These include procuring cells at clinically relevant quantities; the immune acceptance of the cells, which is exacerbated in type 1 diabetes by the resident autoimmunity in the patients; and the fact that diabetes is not an immediately life-threatening disease, so any other therapy will have to be more efficacious and/or less invasive than the current standard treatment of daily blood glucose monitoring and insulin injections.

In general, developing a functional living-tissue replacement requires advances and integration of several types of technology (Nerem and Sambanis, 1995). These are (1) *cell technology*, which addresses the procurement of functional cells at the levels needed for clinical applications; (2) *construct technology*, which involves combining the cells with biomaterials in functional three-dimensional configurations. Construct manufacturing at the appropriate scale, and preservation, as needed for off-the-shelf availability, also fall under this set of technologies; (3) technologies for *in vivo* integration, which address the issues of construct immune acceptance, *in vivo* safety and efficacy, and monitoring of construct integrity and function postimplantation. The same three types of technology need also be developed for a pancreatic substitute. It should be noted, however, that the critical technologies differ, depending on the type of cells used. With allogeneic or xenogeneic islets or beta-cells, the major challenge is the immune acceptance of the implant. In this case, encapsulation of the cells in permselective membranes, which allow passage of low-molecular-weight nutrients and metabolites but exclude larger antibodies and cytotoxic cells of the host, may assist the immune acceptance of the graft. With cell therapies based on potentially autologous nonpancreatic cells, targeted by gene expression vectors *in vivo*, or retrieved surgically,

engineered *ex vivo*, and returned to the host, the major challenge is engineering insulin secretion in precise response to physiologic stimuli. Lastly, with stem or progenitor cells, the primary hurdle is their reproducible differentiation into cells of the pancreatic  $\beta$ -phenotype. Figure 42.1 shows schematically the two general therapeutic approaches based on allo- or xenogeneic cells (Fig. 42.1A) or autologous cells (Fig. 42.1B).

This chapter is therefore organized as follows. We first describe the types of cells that have been used or are of potential use in engineering a pancreatic substitute. We then discuss issues of construct technology, specifically encapsulation methods and the relevant biomaterials, manufacturing issues, and preservation of the constructs. The challenges of *in vivo* integration and results from *in vivo* experiments with pancreatic substitutes are presented next. We conclude by offering a perspective on the current status and the future challenges in developing an efficacious, clinically applicable bioartificial pancreas.

## II. CELL TYPES FOR PANCREATIC SUBSTITUTES

### Islets

Despite several efforts, the *in vitro* expansion of primary human islets has met with limited success. Adult human islets are difficult to propagate in culture, and their expansion leads to dedifferentiation, generally manifested as loss of insulin secretory capacity. Although there exist reports on the redifferentiation of expanded islets (Lechner *et al.*, 2005; Ouziel-Yahalom *et al.*, 2006) and of nonislet pancreatic cells, which are discarded after islet isolation (Todorov *et al.*, 2006), the phenotypic stability and the *in vivo* efficacy of these cells remain unclear. Additionally, with expanded and

redifferentiated islets, it remains unknown whether the insulin-secreting cells arose from the redifferentiation of mature endocrine cells or from an indigenous stem or progenitor cell population in the tissue isolate (Todorov *et al.*, 2006).

Animal, such as porcine, islets are amply available, and porcine insulin is very similar to human, differing by only one amino acid residue. However, the potential use of porcine tissue is hampered by the unlikely but possible transmission of porcine endogenous retroviruses (PERV) to human hosts as well as by the strong xenograft immunogenicity that they elicit. Use of closed, PERV-free herds is reasonably expected to alleviate the first problem. With regard to immunogenicity, a combination of less immunogenic islets, islet encapsulation in permselective barriers, and host immunosuppression may yield long-term survival of the implant. The use of transgenic pigs that do not express the  $\alpha$ -Gal ( $\alpha$ [1,3]-galactose) epitope is one possible approach for reducing the immunogenicity of the islets. Studies also indicate that neonatal pig islets induce a lower T-cell reactivity than adult islets (Bloch *et al.*, 1999), even though the  $\alpha$ -Gal epitope is abundant in neonatal islets as well (Rayat *et al.*, 1998). Furthermore, it is possible that the primary antigenic components in islet tissue are the ductal epithelial and vascular endothelial cells, which express prominently the  $\alpha$ -Gal epitope; on the other hand,  $\beta$ -cells express the epitope immediately after isolation but not after maintenance in culture (Heald *et al.*, 1999). It should also be noted that the large-scale isolation of porcine islets under conditions of purity and sterility that will be needed for eventual regulatory approval pose some major technical hurdles, which have not been addressed yet.

### **$\beta$ -Cell Lines**

Recognizing the substantial difficulties involved with the procurement and amplification of pancreatic islets, several investigators have pursued the development of continuous cell lines, which can be amplified in culture yet retain key differentiated properties of normal  $\beta$ -cells. One of the first successful developments in this area was the generation of the  $\beta$ TC family of insulinomas, derived from transgenic mice carrying a hybrid insulin-promoted simian virus 40 tumor antigen gene; these cells retained their differentiated features for about 50 passages in culture (Efrat *et al.*, 1988). The hypersensitive glucose responsiveness of the initial  $\beta$ TC lines was reportedly corrected in subsequent lines by ensuring expression of glucokinase and of the high- $K_m$  glucose transporter Glut2, and with no or low expression of hexokinase and of the low- $K_m$  transporter Glut1 (Efrat *et al.*, 1993; Knaack *et al.*, 1994). A similar approach was used to develop the mouse MIN-6 cell line that exhibits glucose-responsive secretion of endogenous insulin (Miyazaki *et al.*, 1990). Subsequently, Efrat and coworkers developed the  $\beta$ TC-tet cell line, in which expression of the SV40 T antigen (Tag) oncoprotein is tightly and reversibly regulated by tetracycline. Thus, cells proliferate when Tag is expressed, and

shutting off Tag expression halts cell growth (Efrat *et al.*, 1995; Efrat, 1998). Such reversible transformation is an elegant approach in generating a supply of  $\beta$ -cells via proliferation of an inoculum, followed by arrest of the growth of cells when the desirable population size is reached. When retained in capsules, proliferating cells do not grow uncontrollably, since the dissolved-oxygen concentration in the surrounding milieu can support up to a certain number of viable, metabolically active cells in the capsule volume. This number of viable cells is maintained through equilibration of cell growth and death processes (Papavas *et al.*, 1999a, 1999b). Thus, growth arrest is useful primarily in preventing the growth of cells that have escaped from broken capsules *in vivo* and in reducing the cellular turnover in the capsules. The latter reduces the number of accumulated dead cells in the implant and thus the antigenic load to the host affected by proteins from dead and lysed cells that pass through the capsule material.

In a different approach, Newgard and coworkers (Clark *et al.*, 1997) carried out a stepwise introduction of genes related to  $\beta$ -cell performance into a poorly secreting rat insulinoma (RIN) line. In particular, RIN cells were iteratively engineered to stably express multiple copies of the insulin gene, the glucose transporter Glut2, and the glucokinase gene, which are deemed essential for proper expression of  $\beta$ -cell function. Although this is an interesting methodology, it is doubtful that all genes necessary for reproducing  $\beta$ -cell function can be identified and stably expressed in a host cell. Recently, significant progress was made toward establishing a human pancreatic  $\beta$ -cell line that appears functionally equivalent to normal  $\beta$ -cells (Narushima *et al.*, 2005). This was accomplished through a complicated procedure involving retroviral transfection of primary  $\beta$  cells with the SV40 large T antigen and cDNAs of human telomerase reverse transcriptase. This resulted in a reversibly immortalized human  $\beta$ -cell clone, which secreted insulin in response to glucose, expressed  $\beta$ -cell transcriptional factors, prohormone convertases 1/3 and 2, which process proinsulin to mature insulin, and restored normoglycemia upon implantation in diabetic immunodeficient mice (Narushima *et al.*, 2005).

With regard to  $\beta$ -cell lines capable of proliferation under the appropriate conditions, key issues that remain to be addressed include (1) their long-term phenotypic stability, *in vitro* and *in vivo*; (2) their potential tumorigenicity, if cells escape from an encapsulation device, especially when these cells are allografts that may evade the hosts' immune defenses for a longer period of time than acutely rejected xenografts; and (3) their possible recognition by the autoimmune rejection mechanism in type 1 diabetic hosts.

### **Engineered Non- $\beta$ Pancreatic Cells**

The use of non- $\beta$  pancreatic cells from the same patient, engineered for insulin secretion, relaxes both the cell availability and immune acceptance limitations that exist with other types of cells. It has been shown that the A-chain/

C-peptide and B-chain/C-peptide cleavage sites on the proinsulin gene can be mutated so that the ubiquitous endopeptidase furin recognizes and completely processes proinsulin into mature insulin absent of any intermediates (Yanagita *et al.*, 1992). Based on this concept, several non-endocrine cell lines have been successfully transfected to produce immunoreactive insulin, including hepatocytes, myoblasts, and fibroblasts (Yanagita *et al.*, 1993). In a different approach, Lee and coworkers (2000) expressed a synthetic single-chain insulin analog, which does not require posttranslational processing, in hepatocytes. Although recombinant insulin expression is relatively straightforward, a key remaining challenge is achieving the tight regulation of insulin secretion in response to physiologic stimuli, which is needed for achieving normoglycemia in higher animals and, eventually, humans.

One approach for achieving regulation of insulin secretion is through regulation of biosynthesis at the gene transcription level, as realized in hepatocytes by Thule *et al.* (Thule *et al.*, 2000; Thule and Liu, 2000) and Lee *et al.* (2000). Besides the ability to confer transcriptional-level regulation, hepatocytes are particularly attractive as producers of recombinant insulin due to their high synthetic and secretory capacity and their expression of glucokinase and Glut2 (Cha *et al.*, 2000; Lannoy *et al.*, 2002). Hepatic delivery by viral vectors and expression of the glucose-responsive insulin transgene in diabetic rats controlled the hyperglycemic state for extended periods of time (Lee *et al.*, 2000; Thule and Liu, 2000; Olson *et al.*, 2003). Nevertheless, transcriptional regulation is sluggish, involving long time lags between stimulation of cells with a secretagogue and induced insulin secretion as well as between removal of the secretagogue and down-regulation of the secretory response (Tang and Sambanis, 2003). The latter is physiologically more important, because it means that the cells continue to secrete insulin after glucose has been down-regulated, thus resulting in potentially serious hypoglycemic excursions. Increasing the number of stimulatory glucose elements in a promoter enhances the cellular metabolic responsiveness *in vitro* (Thule *et al.*, 2000). With regard to secretion down-regulation, Tang and Sambanis (2003) hypothesized that the slow kinetics of this process following removal of the transcriptional activator are due to the stability of the preproinsulin mRNA, which continues to become translated after transcription has been turned off. Using a modified preproinsulin cDNA that produced an mRNA with two more copies of the insulin gene downstream of the stop codon resulted in preproinsulin mRNA subjected to nonsense mediated decay and thus destabilized. This significantly expedited the kinetics of secretion down-regulation on turning off transcription (Tang and Sambanis, 2003). Thus, the combination of optimal transcriptional regulation with transgene message destabilization promises further improvements in insulin secretion dynamics from transcriptionally regulated hepatic cells. It should be noted, however, that despite the

time delays inherent in transcriptional regulation, hepatic insulin gene therapy is sufficient to sustain vascular nitric oxide production and inhibit acute development of diabetes-associated endothelial dysfunction in diabetic rats (Thule *et al.*, 2006). Hence, many aspects of the therapeutic potential of hepatic insulin expression remain to be explored.

Another appealing target cell type is endocrine cells, which possess a regulated secretory pathway and the enzymatic machinery needed to process authentic proinsulin into insulin. Early work in this area involved expression of recombinant insulin in the anterior pituitary mouse AtT-20 cell line (Moore *et al.*, 1983), which can be subjected to repeated episodes of induced insulin secretion using nonmetabolic secretagogues (Sambanis *et al.*, 1990). Cotransfection with genes encoding the glucose transporter Glut-2 and glucokinase resulted in glucose-responsive insulin secretion (Hughes *et al.*, 1992, 1993). However, limitations of this approach include possible instabilities in the cellular phenotype and the continued secretion of endogenous hormones, such as adrenocorticotrophic hormone from AtT-20 cells, which are not compatible with prandial metabolism.

In this regard, endocrine cells of the intestinal epithelium, or enteroendocrine cells, are especially promising. Enteroendocrine cells secrete their incretin products in a tightly controlled manner that closely parallels the secretion of insulin following oral glucose load in human subjects; incretin hormones are fully compatible with prandial metabolism and glucose regulation (Schirra *et al.*, 1996; Kieffer and Habener, 1999). As with  $\beta$ -cells, enteroendocrine cells are polar, with sensing microvilli on their luminal side and secretory granules docked at the basolateral side, adjacent to capillaries. Released incretin hormones include the glucagon-like peptides (GLP-1 and GLP-2) from intestinal L-cells and glucose-dependent insulinotropic polypeptide (GIP) from K-cells, which potentiate insulin production from the pancreas after a meal (Drucker, 2002). The importance of enteroendocrine cells (and, in particular, L-cells) was first put forward by Creutzfeldt (1974), whose primary interest in these cells was for the prospect of using GLP-1 for the treatment of type 2 diabetes. Furthermore, groundbreaking work by Cheung *et al.* (2000) demonstrated that insulin produced and secreted by genetically modified intestinal K-cells of transgenic mice prevented the animals from becoming diabetic after injection with streptozotocin (STZ), which specifically kills the  $\beta$ -cells of the pancreas. This is an important proof-of-concept study, which showed that enteroendocrine cell-produced insulin can provide regulation of blood glucose levels. Subsequent work with a human intestinal L-cell line demonstrated that these cells can be effectively transduced to express recombinant human insulin, which colocalizes in secretory vesicles with endogenous GLP-1 and thus is secreted with identical kinetics to GLP-1 in response to stimuli (Tang and Sambanis, 2003,

2004). The intestinal tract could be considered an attractive target for gene therapy because of its large size, making it the largest endocrine organ in the body (Wang *et al.*, 2004); however, enteroendocrine cell gene therapy faces serious difficulties due to anatomic complexity, with the enteroendocrine cells being located at the base of invaginations of the gut mucosa called *crypts*, the very harsh conditions in the stomach and intestine, and the rapid turnover of the intestinal epithelium.

Contrary to direct *in vivo* gene delivery, *ex vivo* gene therapy involves retrieving the target cells surgically, culturing them and possibly expanding them *in vitro*, genetically engineering them to express the desired properties, and then returning them to the host, either as such or in a three-dimensional tissue substitute. It is generally thought that the *ex vivo* approach is advantageous, for it allows for the thorough characterization of the genetically engineered cells prior to implantation, possibly for the preservation of some of the cells for later use by the same individual and, importantly, for localization and retrievability of the implant. However, the challenges imposed by the *ex vivo* approach, including the surgical retrieval, culturing, and *in vitro* genetic engineering of the target cells are significant, so such methods are currently under development.

### Differentiated Stem or Progenitor Cells

Naturally, throughout life, islets turn over slowly, and new, small islets are continually generated from ductal progenitors (Finegood *et al.*, 1995; Bonner-Weir and Sharma, 2002). There is also considerable evidence that adult pluripotent stem cells may be a possible source of new islets (Bonner-Weir *et al.*, 2000; Ramiya *et al.*, 2000; Kojima *et al.*, 2003). However, efforts to regenerate  $\beta$ -cells *in vitro* or *in vivo* by differentiation of embryonic or adult stem or pancreatic progenitor cells have produced mixed results. Insulin-producing, glucose-responsive cells, as well as other pancreatic endocrine cells, have been generated from mouse embryonic stem cells (Lumelsky *et al.*, 2001). Insulin-secreting cells obtained from embryonic stem cells reversed hyperglycemia when implanted in mice rendered diabetic by STZ injection (Soria *et al.*, 2000). In another study, mouse embryonic stem cells transfected to express constitutively Pax4, a transcription factor essential for  $\beta$ -cell development, differentiated into insulin-producing cells and normalized blood glucose when implanted in STZ-diabetic mice (Blyszczuk *et al.*, 2003). On the other hand, other studies do not support differentiation of embryonic stem cells into the  $\beta$ -cell phenotype (Rajagopal *et al.*, 2003). Overall, the mixed and somewhat inconsistent results point to the considerable work that needs to be done before stem or progenitor cells can be reliably differentiated into  $\beta$  cells at a clinically relevant scale. Harnessing the *in vivo* regenerative capacity of the pancreatic endocrine system may present a promising alternative approach.

### Engineering of Cells for Enhanced Survival *In Vivo*

Because islets and other insulin-secreting cells experience stressful conditions during *in vitro* handling and *in vivo* postimplantation, several strategies have been implemented to enhance islet or nonislet cell survival in pancreatic substitutes. Strategies generally focus on improving the immune acceptance of the graft, enhancing its resistance to cytokines, and reducing its susceptibility to apoptosis. Phenotypic manipulations include extended culturing of neonatal and pig islets at 37°C, which apparently reduces their immunogenicity, possibly by down-regulating the major histocompatibility class 1 antigens on the islet surface; islet pretreatment with TGF- $\beta$ 1; and enzymatic treatment of pig islets with  $\alpha$ -galactosidase to reduce the  $\alpha$ -galactosyl epitope on islets (Prokop, 2001). However, the permanency of these modifications is unknown. For instance,  $\alpha$ -galactosyl epitopes reappear on islets 48 hours after treatment with  $\alpha$ -galactosidase. With proliferative cell lines destined for recombinant insulin expression, selection of clones resistant to cytokines appears feasible (Chen *et al.*, 2000). Gene chip analysis of resistant cells may then be used to identify the genes responsible for conferring cytokine resistance.

Genetic modifications for improving survival *in vivo* may offer prolonged expression of the desired properties relative to phenotypic manipulations, but they also present the possibility of modifying the islets in additional, undesirable ways. Notable among the various proposed approaches, reviewed in Jun and Yoon (2005), are the expression of the immunomodulating cytokines IL-4 or a combination of IL-10 and TGF- $\beta$ , which promoted graft survival by preventing immune attack in mice; and the expression of the antiapoptotic bcl-2 gene using a replication defective herpes simplex virus, which resulted in protection of  $\beta$ -cells from a cytokine mixture of interleukin-1 $\beta$ , TNF- $\alpha$ , and IFN- $\gamma$  *in vitro*.

## III. CONSTRUCT TECHNOLOGY

Construct technology focuses on associating cells with biocompatible materials in functional three-dimensional configurations. Depending on the type of cells used, the primary function of the construct can be one or more of the following: to immunoprotect the cells postimplantation, to enable cell function, to localize insulin delivery *in vivo*, or to provide retrievability of the implanted cells.

### Encapsulated Cell Systems

Encapsulation for immunoprotection involves surrounding the cells with a permselective barrier, in essence an ultrafiltration membrane, which allows passage of low-molecular-weight nutrients and metabolites, including insulin, but excludes larger antibodies and cytotoxic cells of the host. Figure 42.2 summarizes the common types of encapsulation devices, which include spherical microcapsules, tubular or planar diffusion chambers, thin sheets, and vascular devices.

**FIG. 42.2.** Schematics of commonly used encapsulation devices for insulin-secreting cells. Vascular devices and membrane chambers of tubular, planar, or sheet architectures are generally referred to as macrocapsules, in distinction from the much smaller microcapsules.

Encapsulation can be pursued via one of two general approaches. With capsules fabricated using water-based chemistry, cells are first suspended in un-cross-linked polymer, which is then extruded as droplets into a solution of the cross-linking agent. A typical example here is the very commonly used alginate encapsulation. Alginate is a complex mixture of polysaccharides obtained from seaweeds, which forms a viscous solution in physiologic saline. Islets or other insulin-secreting cells are suspended in sodium alginate, and droplets are extruded into a solution of calcium chloride. Calcium cross-links alginate, instantaneously trapping the cells within the gel. The size of the droplets, hence also of the cross-linked beads, can be controlled by flowing air parallel to the extrusion needle so that droplets detach at a smaller size than if they were allowed to fall by gravity; or by using an electrostatic droplet generator, in which droplets are detached from the needle by adjusting the electrostatic potential between the needle and the calcium chloride bath. Capsules generated this way can have diameters from a few hundred micrometers to more than one millimeter. Alginate by itself is relatively permeable; to generate the permselective barrier, beads are treated with a polycationic solution, such as poly-L-lysine or poly-L-ornithine. The reaction time between alginate and the polycation determines the molecular weight cutoff of the resulting membrane. Poly-L-lysine is highly inflammatory *in vivo*, however, so beads are coated with a final layer of alginate to improve their biocompatibility. Hence, calcium alginate/poly-L-lysine/alginate (APA) beads are finally formed. Treating the beads with a calcium chelator, such as citrate, presumably liquefies the inner core, forming APA membranes. Other materials that have been used for cell microencapsulation include agarose, photo-cross-linked poly(ethylene glycol), and (ethyl methacrylate, methyl methacrylate, and dimethylaminoethyl methacrylate) copolymers (Mikos *et al.*, 1994; Sefton and Kharlip, 1994). Advantages of hydrogel microcapsules include a high surface-to-volume ratio, and thus good transport proper-

ties, as well as ease of handling and implantation. Small beads can be implanted in the peritoneal cavity of animals simply by injection, without the need for incision. Other common implantation sites include the subcutaneous space and the kidney capsules. Disadvantages include the fragility of the beads, especially if the cross-linking cation becomes chelated by compounds present in the surrounding milieu or released by lysed cells, and the lack of easy retrievability once the beads have been dispersed in the peritoneal cavity of a host. Earlier problems caused by the variable composition of alginates and the presence of endotoxins have been resolved through the development and commercial availability of ultrapure alginates of well-defined molecular weight and composition (Sambanis, 2000; Stabler *et al.*, 2001).

Hydrogels impose little diffusional resistance to solutes, and indeed effective diffusivities in calcium alginate and agarose hydrogels are in the range of 50–100% of the corresponding diffusivities in water (Tziampazis and Sambanis, 1995; Lundberg and Kuchel, 1997). However, with conventional microencapsulation, the volume of the hydrogel contributes significantly to the total volume of the implant. For example, with a 500- $\mu\text{m}$  microcapsule containing a 300- $\mu\text{m}$  islet, the polymer volume constitutes 78% of the total capsule volume. Additionally, conventional microcapsules may not be appropriate for hepatic portal vein implantation because, besides their higher implant volume relative to the same number of naked islets, they may result in higher portal vein pressure and more incidences of blood coagulation in the liver. To address this problem, methods have been developed for islet encapsulation in thin conformal polymeric coats. Materials that have been used for conformal coating include photopolymerized poly(ethylene glycol) diacrylate (Hill *et al.*, 1997; Cruise *et al.*, 1999) and hydroxyethyl methacrylate-methyl methacrylate (HEMA-MMA) (May and Sefton, 1999; Sefton *et al.*, 2000).

Encapsulated cell systems can also be fabricated by preforming the permselective membrane in a tubular or disc-

shaped configuration, filling the construct with a suspension of islets or other insulin-secreting cells in an appropriate extracellular matrix, and then sealing the device. This approach is particularly useful when organic solvents or other chemicals harsh to the cells are needed for the fabrication of the membranes. Membrane chambers can be of tubular or planar geometry (Fig. 42.2). The cells are surrounded by the semipermeable membrane and can be implanted intraperitoneally, subcutaneously, or at other sites. Membrane materials used in fabricating these devices include polyacrylonitrile-polyvinyl chloride (PAN-PVC) copolymers, polypropylene, polycarbonate, cellulose nitrate, and polyacrylonitrile-sodium methallylsulfonate (AN69) (Lanza *et al.*, 1992; Mikos *et al.*, 1994; Prevost *et al.*, 1997; Delaunay *et al.*, 1998; Sambanis, 2000). Typical values of device thickness or fiber diameter are 0.5–1 mm. Advantages of membrane chambers are the relative ease of handling, the flexibility with regard to the matrix in which the cells are embedded, and retrievability after implantation. A major disadvantage is their inferior transport properties, since the surface-to-volume ratio is smaller than that of microcapsules and diffusional distances are longer.

Constructs connected to the vasculature via an arterio-venous shunt consist of a semipermeable tube surrounded by the cell compartment (Fig. 42.2). The tube is connected to the vasculature, and transport of solutes between the blood and the cell compartment occurs via the pores in the tube wall. A distinct advantage of the vascular device is the improved transport of nutrients and metabolites, which occurs by both diffusion and convection. However, the major surgery that is needed for implantation and problems of blood coagulation at the anastomosis sites have considerably reduced enthusiasm for these devices.

### Other Construct Systems

A common approach for improving the oxygenation of cells in diffusion chambers is to encourage the formation of neovasculature around the implant. This is discussed in the following “*In Vivo* Implantation” section. Other innovative approaches that have been proposed include the electrochemical generation of oxygen in a device adjacent to a planar immunobarrier diffusion chamber containing the insulin-secreting cells (Wu *et al.*, 1999); and the coencapsulation of islets with algae, where the latter produce oxygen photosynthetically upon illumination (Bloch *et al.*, 2006). These were *in vitro* studies, however, and the ability to translate these approaches to effective *in vivo* configurations remains unknown.

In a different design, Cheng *et al.* (2004, 2006) combined constitutive insulin-secreting cells with a glucose-responsive material in a disc-shaped construct. As indicated earlier, it is straightforward to genetically engineer non- $\beta$ -cells for constitutive insulin secretion; the challenge is in engineering appropriate cellular responsiveness to

physiologic stimuli. In this proposed device, a concanavalin A (con A)-glycogen material, sandwiched between two ultrafiltration membranes, acted as a control barrier to insulin release from an adjacent compartment containing the cells. Specifically, con A-glycogen formed a gel at a low concentration of glucose, which was reversibly converted to sol at a high glucose concentration, as glucose displaced glycogen from the gel network. Since insulin diffusivity is higher through the sol than through the gel, insulin released by the cells during low-glucose periods diffused slowly through the gel material; when switched to high glucose, the insulin accumulated in the cell compartment during the previous cycle was released at a faster rate through the sol-state polymer. Overall, this approach converted the constitutive secretion of insulin by the cells to a glucose-responsive insulin release by the device (Cheng *et al.*, 2006). Again, these were *in vitro* studies, and the *in vivo* efficacy of this approach remains to be evaluated.

### Construct Design and *In Vitro* Evaluation

Design of three-dimensional encapsulated systems can be significantly enabled using mathematical models of solute transport through the tissue and of nutrient consumption and metabolite production by the cells. Beyond the microvasculature surrounding the construct, transport of solutes occurs by diffusion, unless the construct is placed in a flow environment, in which case convective transport may also occur. Due to its low solubility, transport of oxygen to the cells is the critical issue. Models can be used to evaluate the dimensions and the cell density within the construct so that all cells are sufficiently nourished and the capsule as a whole is rapidly responsive to changes in the surrounding glucose concentration (Tziampazis and Sambanis, 1995). Experimental and modeling methods for determining transport properties and reaction kinetics have been described previously (Sambanis and Tan, 1999). Furthermore, models can be developed to account for the cellular reorganization that occurs in constructs with time as a result of cell growth, death, and possibly migration processes. Such reorganization is especially significant when proliferating insulin-secreting cell lines are encapsulated in hydrogel matrices (Stabler *et al.*, 2001; Simpson *et al.*, 2005; Gross *et al.*, 2007).

Pancreatic tissue substitutes should be evaluated *in vitro* prior to implantation, in terms of their ability to support the cells within over prolonged periods of time and to exhibit and maintain their overall secretory properties. Long-term cultures can be performed in perfusion bioreactors under conditions simulating aspects of the *in vivo* environment. In certain studies, the bioreactors and support perfusion circuits were made compatible with a nuclear magnetic resonance spectrometer. This allowed measuring intracellular metabolites, such as nucleotide triphosphates, as a function of culture conditions and time, without the need

to extract the encapsulated cells (Papas *et al.*, 1999a, 1999b). Such studies produce a comprehensive understanding of the intrinsic tissue function in a well defined and controlled environment prior to introducing the additional complexity of host-implant interactions in *in vivo* experiments.

The secretory properties of tissue constructs can be evaluated with low time resolution in simple static culture experiments by changing the concentration of glucose in the medium and measuring the secreted insulin. In general, a square wave of insulin concentration is implemented, from basal to inducing basal conditions for insulin secretion. To evaluate the secretory response with a higher time resolution, perfusion experiments need to be performed, in which medium is flowed around the tissue and secreted insulin is assayed in the effluent. Again, a square wave of glucose concentration is generally implemented. By comparing the secretory dynamics of free and encapsulated cells, one can ensure that the encapsulation material does not introduce excessive time lags that might compromise the secretory properties of the construct. Indeed, properly designed hydrogel microcapsules introduce only minimal secretory time lags (Tziampazis and Sambanis, 1995; Sambanis *et al.*, 2002).

### Manufacturing Considerations

Fabrication of pancreatic substitutes of consistent quality requires the use of cells that are also of consistent quality. Although with clonal, expandable cells this is a rather straightforward issue, with islets isolated from human and animal tissues there can be significant variability in the quantity and quality of the cells in the preparations. With islets from cadaveric human donors, the quality of the isolates is assessed by microscopic observation, viability staining, and possibly a static insulin secretion test. It is generally recognized, however, that a quantitative, objective assessment of islet quality would help improve the consistency of the preparations and thus, possibly, the transplantation outcome.

It is conceivable that encapsulated cell systems could be fabricated at a central location from which they are distributed to clinical facilities for implantation. In this scheme, preservation of the constructs for long-term storage, inventory management, and, importantly, sterility control would be essential. Cryopreservation appears to be a promising method for maintaining fabricated constructs for prolonged time periods. Although there have been significant studies on the cryopreservation of single cells and some tissues, the problems pertaining to cryopreserving artificial tissues are only beginning to be addressed. Cryopreservation of macroencapsulated systems is expected to be particularly challenging and has not been reported in the literature. However,  $\beta$ TC-cells encapsulated in alginate beads have been preserved successfully (Mukherjee *et al.*, 2005; Song *et al.*, 2005). An especially promising approach involves using high concentrations of cryoprotective agents so that water is

converted to a glassy, or vitrified, state at low temperatures; the absence of ice crystals in both the intracellular and extracellular domains appears helpful in maintaining not only cellular viability but also the structure and function of the surrounding matrix (Mukherjee *et al.*, 2005; Song *et al.*, 2005).

## IV. IN VIVO IMPLANTATION

This section highlights results from *in vivo* experiments using the different configurations outlined earlier. Results with encapsulated cell systems are presented first. Since *in vivo* experiments with non- $\beta$ -cells engineered for insulin secretion are at present based mostly on *in vivo* gene therapy approaches, these are described next. Technologies for the *in vivo* monitoring of cells and constructs and the issue of implant retrievability are then discussed.

### Encapsulated Cell Systems

*In vivo* experiments with pancreatic substitutes are numerous in small animals, limited in large animals, and few in humans. Allogeneic and xenogeneic islets in hydrogel microcapsules implanted in diabetic mice and rats have generally restored normoglycemia for prolonged periods of time. In the early study of O'Shea *et al.* (1984), islet allografts encapsulated in APA membranes were implanted intraperitoneally in streptozotocin-induced diabetic rats. Of the five animals that received transplants, three remained normoglycemic for more than 100 days. One of these three animals remained normoglycemic 368 days postimplantation. In the later study of Lum *et al.* (1992), rat islets encapsulated in APA membranes and implanted in streptozotocin diabetic mice restored normoglycemia for up to 308 days, with a mean xenograft survival time of 220 days. With all recipients, normoglycemia was restored within two days postimplantation. Control animals receiving single injections of unencapsulated islets remained normoglycemic for less than two weeks (O'Shea *et al.*, 1984; Lum *et al.*, 1992). More recently, APA-encapsulated  $\beta$ TC6-F7 insulinomas restored normoglycemia in diabetic rats for up to 60 days (Mamujee *et al.*, 1997), and APA-encapsulated  $\beta$ TC-tet insulinomas in NOD mice for at least eight weeks (Black *et al.*, 2006). In the latter study, it was also observed that no host cell adherence occurred to microcapsules, and there were no significant immune responses to the implant, with cytokine levels being similar to those of sham-operated controls. These results are thus indicative of the potential use of an immunisolated continuous  $\beta$ -cell line for the treatment of diabetes. With the recently developed human cell line (Narushima *et al.*, 2005), experiments were performed with unencapsulated cells transplanted into streptozotocin-induced diabetic severe combined immunodeficiency mice. Control of blood glucose levels started within two weeks postimplantation, and mice remained normoglycemic for longer than 30 weeks (Narushima *et al.*, 2005). Besides rodents, long-term restoration of normoglycemia with microencapsulated islets

has been demonstrated in large animals, including spontaneously diabetic dogs, where normoglycemia was achieved with canine islet allografts for up to 172 days (Soon-Shiong *et al.*, 1992), and monkeys, where in one animal porcine islet xenografts normalized hyperglycemia for more than 150 days (Sun *et al.*, 1992). More recently, one of the companies working on islet encapsulation technology announced that primate subjects in ongoing studies have continued to exhibit improved glycemic regulation over a six-month period after receiving microencapsulated porcine islet transplants (MicroIslet Inc. Press Release, August 7, 2006).

*In vivo* results with vascular devices are reportedly mixed. Implantation of devices containing allogeneic islets as arteriovenous shunts in pancreatectomized dogs resulted in 20–50% of the dogs becoming normoglycemic up to 10 weeks postimplantation without exogenous insulin administration. When xenogeneic bovine or porcine islets were used, only 10% of the dogs remained normoglycemic 10 weeks postimplantation. All dogs were reported diabetic or dead after 15 weeks (Sullivan *et al.*, 1991). Recently, a hollow-fiber device composed of polyethylene-vinyl alcohol fibers and a poly-amino-urethane-coated, nonwoven polytetrafluoroethylene fabric seeded with porcine islets provided normalization of the blood glucose levels in totally pancreatectomized pigs when connected to the vasculature of the animals (Ikeda *et al.*, 2006). It should be noted, however, that the overall interest in vascular devices has faded, due to the surgical and blood coagulation challenges they pose.

Although several hypotheses exist, the precise cause of the eventual *in vivo* failure of encapsulated cell systems remains unclear. Encapsulation does not completely prevent the immune recognition of the implant. Although direct cellular recognition is prevented, antigens shed by the cells as a result of secretion and, more importantly, lysis in the capsules eventually pass through the permselective barrier and are recognized by the antigen-presenting cells of the host. For example, in one study, antibodies against islets in a tubular diffusion chamber were detected in plasma two to six weeks postimplantation, suggesting that islet antigens crossed the membrane and stimulated antibody formation in the host (Lanza *et al.*, 1994). In another study, alginate-encapsulated islets were lysed *in vitro* by nitric oxide produced by activated macrophages (Wiegand *et al.*, 1993). Passage of low-molecular-weight molecules cannot be prevented by immunoprotective membranes imposing a molecular weight cutoff on the order of 50 kDa. It should be noted that in one human study involving encapsulated allogeneic islets, the patient had to be provided with low levels of immunosuppression (Soon-Shiong *et al.*, 1994). In a more recent report, also with encapsulated allografts implanted peritoneally, type 1 diabetic patients remained nonimmunosuppressed but were unable to withdraw exogenous insulin (Calafiore *et al.*, 2006).

Nonspecific inflammation may also occur around the implant and develop into a fibrous capsule, reducing the

oxygen available to the cells within. The fibrotic layer has been found to consist of several layers of fibroblasts and collagen with polymorphonuclear leukocytes, macrophages, and lymphocytes. The surface roughness of the membrane may also trigger inflammatory responses. In one study, membranes with smooth outside surfaces exhibited a minimal fibrotic reaction 10 weeks postimplantation, regardless of the type of encapsulated cells, whereas rough surfaces elicited a fibrotic response even one week postimplantation (Lanza *et al.*, 1991). Use of high-purity materials also helps to minimize inflammatory reactions. If a material is intrinsically inflammatory, such as poly-L-lysine, it can be coated with a layer of noninflammatory material, such as alginate, to minimize the host's reaction. Such coverage may not be sufficiently permanent, though, resulting in the eventual fibrosis of the implant. Indeed, several investigators report improved results with plain alginate beads without a poly-L-lysine layer, especially when allogeneic cells are used in the capsules.

Provision of nutrients to and removal of metabolites from encapsulated cells can be especially challenging *in vivo*. Normal pancreatic islets are highly vascularized and thus well oxygenated. There exists evidence that unencapsulated islets injected in the portal system of the liver become revascularized, which enhances their engraftment and function. On the other hand, encapsulation prevents revascularization, so the implanted tissue is nourished by diffusion alone. Promotion of vascularization around the immunoprotective membrane increases the oxygenation of the implanted islets (Prokop *et al.*, 2001). Interestingly, transformed cells, such as the  $\beta$ TC3 line of mouse insulinomas, are more tolerant of hypoxic conditions than intact islets; such cells may thus function better than islets in implanted capsules (Papavas *et al.*, 1996). However, with transformed cells, too, enhanced oxygenation increases the density of functional cells that can be effectively maintained within the implant volume. Vascularization is dependent on the microarchitecture of the material, which should have pores 0.8–8.0  $\mu$ m in size, allowing permeation of host endothelial cells (Brauker *et al.*, 1992, 1995). Vascularization is also enhanced by the delivery of angiogenic agents, such as FGF-2 and VEGF, possibly with controlled-release devices (Sakurai *et al.*, 2003). Although vascularization can be promoted around a cell-seeded device, improved success has been reported if a cell-free device is first implanted and vascularized and the cells are then introduced. One example of this procedure involved placing a cylindrical stainless steel mesh in the subcutaneous space of rats, with the islets introduced 40 days later (Pileggi *et al.*, 2006). Replacement of a vascularized implant is challenging, however, due to the bleeding that occurs. A solution to this problem may entail the design of a device that can be emptied and refilled with a suspension of cells in an extracellular matrix without disturbing the housing and the associated vascular network.

## Gene and Cell-Based Therapies

*In vivo* efficacy studies with gene therapy and non- $\beta$ -cells genetically engineered for insulin secretion are generally limited to small animals. Intraportal injection of recombinant adenovirus expressing furin-compatible insulin under the control of a glucose-responsive promoter containing elements of the rat liver pyruvate kinase gene restored near-normal glycemia in streptozotocin diabetic rats for periods of 1–12 weeks (Thule and Liu, 2000). With hepatic delivery of a recombinant adeno-associated virus expressing a single-chain insulin analog under the control of an L-type pyruvate kinase promoter, Lee and coworkers (2000) controlled blood glucose levels in streptozotocin diabetic rats and NOD mice for periods longer than 20 weeks. However, transiently low blood glucose levels observed three to five hours after glucose loading indicated a drawback of the transcriptional regulation of insulin expression, which may result in hypoglycemic episodes (Lee *et al.*, 2000). Possible approaches toward ameliorating this problem include optimizing the number of glucose-regulatory and insulin-sensing elements in the promoter (Jun and Yoon, 2005) and destabilizing the preproinsulin mRNA; the latter has been shown to expedite significantly the down-regulation of secretion dynamics from transcriptionally controlled cells on removal of the secretory stimulus (Tang and Sambanis, 2003).

*In vivo* gene therapy with small animals has also shown success when the target cells for insulin expression were intestinal endocrine K- or gastric G-cells. Using a transgene expressing human insulin under the control of the glucose-dependent insulinotropic peptide (GIP) promoter, Cheung *et al.* (2000) expressed insulin specifically in gut K-cells of transgenic mice, which protected them from developing diabetes following STZ-mediated destruction of the native  $\beta$ -cells. Similarly, use of a tissue-specific promoter to express insulin in gastric G-cells of mice resulted in insulin release into circulation in response to meal-associated stimuli, suggesting that G-cell insulin expression is beneficial in the amelioration of diabetes (Lu *et al.*, 2005). Translation of these approaches to adult animals and, eventually, humans, requires the development of effective methods of gene delivery to intestinal endocrine or gastric cells *in vivo* or the development of effective *ex vivo* gene therapy approaches.

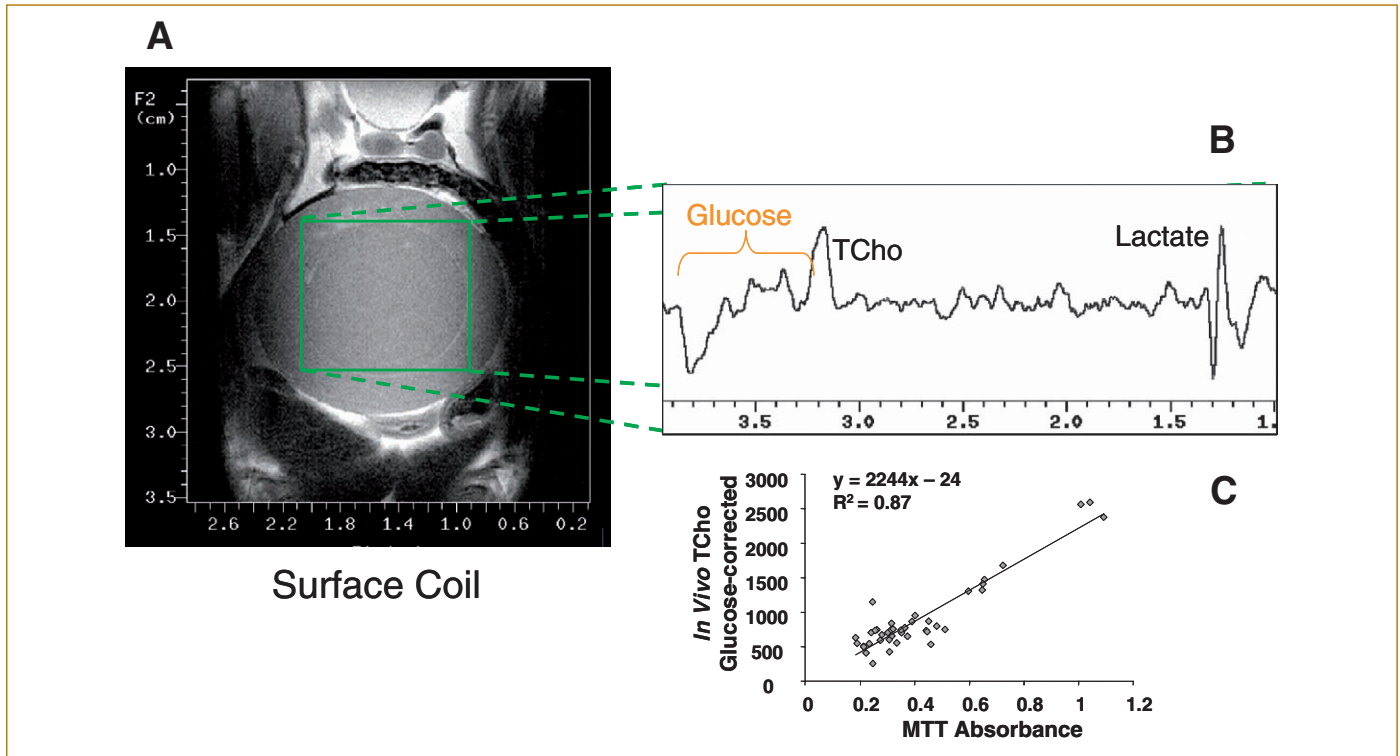

## In Vivo Monitoring

Monitoring of the number and function of insulin-secreting cells *in vivo* would provide valuable information directly on the implant and possibly offer early indications of implant failure. Additionally, in animal experiments, the ability to monitor an implant noninvasively reduces the number of animals that are needed in the experimental design and helps establish a critical link between implantation and endpoint physiologic effects, the latter commonly being blood glucose levels and animal weight.

Imaging techniques can provide unique insight into the structure/function relationship of a construct *in vitro* and *in vivo*. There are several imaging modalities that have been applied to monitor tissue-engineered constructs, including computed tomography (CT), positron emission tomography (PET), optical techniques, and nuclear magnetic resonance (NMR) imaging and spectroscopy. Among these, NMR offers the unique advantage of providing information on both construct integrity and function, without the need to modify the cells genetically (e.g., through the expression of green fluorescent protein, used in optical methods) or the introduction of radioactive labels (e.g., PET agents). Furthermore, since magnetic fields penetrate uniformly throughout the sample, NMR is ideally suited to monitor constructs implanted at deep-seated locations. Its disadvantage is its low sensitivity. Whereas optical and radionuclide techniques can detect tracer quantities, NMR detects metabolites that are available in the millimolar or, in some cases, submillimolar range.

The ability to monitor noninvasively *in vivo* a pancreatic substitute by NMR was reported recently (Stabler *et al.*, 2005). Agarose disc-shaped constructs containing mouse insulinoma  $\beta$ TC3-cells were implanted in the peritoneal cavity of mice. Construct integrity was visualized by MR imaging and the metabolic activity of the cells within by water-suppressed  $^1\text{H}$  NMR spectroscopy (Fig. 42.3). Control experiments established that the total choline (TCho) resonance at 3.2 ppm, which is attributed to three choline metabolites, correlated positively and linearly with the number of viable cells within the construct, measured with an independent assay. To obtain the TCho signal *in vivo* without interference from the surrounding host tissue, such as peritoneal fat, the central agarose disc containing the cells had to be surrounded by cell-free agarose buffer zones. This ensured that the MR signal arose only from the implanted cells, even as the construct moved due to animal breathing. A second problem that had to be resolved was that glucose diffusing into the construct produced a resonance that interfered with the TCho resonance at 3.2 ppm. For this, a unique glucose resonance at 3.85 ppm was used to correct for the interference at 3.2 ppm so that a corrected signal, uniquely attributed to TCho, could be obtained. The latter correlated positively and linearly with the number of viable cells, measured with an independent assay, on the constructs postexplantation (Fig. 42.3). Hence, with the appropriate implanted construct architecture and signal processing, the number of viable cells in an implant could be followed in the same animal as a function of time (Stabler *et al.*, 2005).

Labeling of cells with magnetic nanoparticles, which can be detected by magnetic resonance, and genetically engineering cells so that they express a fluorescent or luminescent marker that can be optically detected are other methods being pursued to track the location and possibly function of implanted cells *in vivo*. It is expected that development of robust monitoring methodologies will be helpful

**FIG. 42.3.** Magnetic resonance imaging and localized spectroscopy of a disc-shaped agarose construct containing  $\beta$ TC3 mouse insulinoma cells at an initial density of  $7 \times 10^7$  cells/mL agarose implanted in the peritoneal cavity of a mouse. **(A)**  $^1\text{H}$  NMR image obtained with a surface coil. The inner disc, containing the cells, is distinguishable from the surrounding cell-free buffer zone, implemented to exclude spectroscopic signal from the surrounding host tissue. **(B)** Localized, water-suppressed  $^1\text{H}$  NMR spectrum from the cells contained in the inner disc. Resonances due to total choline (TCho), glucose, and lactate are clearly visible. The time needed to collect the spectrum was 13 min. **(C)** Correlation between the glucose-corrected TCho resonance at 3.2 ppm and the viable cell number obtained postexplantation using the MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide] assay. Adapted from Stabler *et al.* (2005).

not only in experimental development studies but also in eventual clinical applications.

### Retrievability

The issue of construct retrievability needs to be considered for all pertinent applications. Useful lifetimes of constructs are limited, so repeated implantation of cells will be required. It is as yet unclear whether retrieval of constructs will be necessary at the end of their useful lives. Long-term studies on the safety challenges posed by accumulated implants in the host need to be carried out to address this question.

## V. CONCLUDING REMARKS

Tight glycemic regulation in insulin-dependent diabetics significantly improves their overall health and reduces the long-term complications of the disease. A pancreatic substitute holds significant promise at accomplishing this in a relatively noninvasive way. However, to justify the improved outcome, a substitute needs to be not only efficacious in terms of insulin secretion, but also immunologically acceptable. A number of approaches are being pursued

to address this obstacle and additionally develop constructs that can be manufactured at a clinically relevant scale. However, as the problems are being thoroughly investigated, their solutions become more challenging. Encapsulation in permselective barriers improves the immune acceptance of allo- and xenografts, but it is doubtful that encapsulation will, by itself, ensure the long-term survival and function of the implant in nonimmunosuppressed hosts. The development of specific, benign immune suppression protocols that work in concert with encapsulation appears necessary. Reducing the immunogenicity of the implanted cells and modifying them so that they better withstand the encapsulation and *in vivo* environment are appropriate strategies. To ensure that substitutes can be fabricated at the necessary scale, methods to expand pancreatic islets in culture, to produce  $\beta$ -cells from stem cells, or to generate expandable  $\beta$ -cell lines with appropriate phenotypic characteristics need to be pursued. In alternative approaches involving gene therapy of non- $\beta$ -cells, or the *ex vivo* engineering of non- $\beta$ -cells retrieved surgically from the host, the major problem is not that of cell procurement or immune acceptance but, rather, of ensuring precise regulation of insulin

secretion by glucose or other physiologic stimuli. This poses a different set of problems, which, however, are equally challenging to those of  $\beta$ -cell procurement and immune acceptance. Methods for the preservation of substitutes and for the noninvasive monitoring of their integrity and functionality *in vivo* are integral parts of construct development and characterization with regard to construct manufacturing and assessment of *in vivo* efficacy, respectively.

As in many aspects of life, with challenges come opportunities. It is essential that multiple approaches be pursued in parallel, because it is currently unclear which ones will

eventually develop into viable therapeutic procedures. If more than one method evolves into a clinical application, this would be welcome news, because it may allow flexibility in the personalization of therapy. For instance, in an adult type 2 insulin-dependent diabetic, use of an encapsulated allograft with low-level immunosuppression might constitute an appropriate therapeutic modality. In a juvenile type 1 diabetic with aggressive autoimmunity, however, use of autologous genetically engineered non- $\beta$ -cells, which are not recognized by the resident autoimmunity, may constitute the therapeutic method of choice.

## VI. ACKNOWLEDGMENTS

The studies in the author's and coinvestigators' laboratories referenced in this chapter were supported by grants from the Georgia Tech/Emory Center for the Engineering of Living Tissues (GTEC), a National Science Foundation Engineering Research Center; and by grants from the National Institutes

of Health, EmTech Bio, and the Juvenile Diabetes Research Foundation international. The author also wishes to thank Indra Neil Mukherjee and Heather Bara for critically reviewing the manuscript, as well as Drs. Constantinidis and Thulé for helpful discussions.

### I. INTRODUCTION

The use of islet transplantation as a treatment for diabetes has been hampered by the limited availability of human islets; therefore, new sources of insulin-producing cells are needed. Expansion of beta-cells by the generation of reversibly immortalized beta-cells and creation of insulin-producing cells by exogenous expression of insulin in non-beta-cells have been investigated as new sources of beta-cells. Recently, embryonic and adult stem cells or pancreatic progenitor cells have been engineered to differentiate into insulin-producing cells, demonstrating the possible use of these cells for beta-cell replacement. Despite significant progress, further studies are needed to generate truly functional insulin-producing cells. In addition, the engineering of beta-cells to protect them from immune attack and to improve viability has been tried. Although the usefulness of engineered beta-cells has yet to be clinically proven, studies utilizing different engineering strategies and careful analysis of the resulting insulin-producing cells may offer potential methods to cure diabetes.

Diabetes mellitus is a metabolic disease characterized by uncontrolled hyperglycemia, which results in long-term clinical problems, including retinopathy, neuropathy, nephropathy, and heart disease. Diabetes affects over 150 million people worldwide and is considered an epidemic of the 21st century. Blood glucose homeostasis is controlled by endocrine beta-cells, located in the islets of Langerhans in

the pancreas. When the concentration of blood glucose rises after a meal, insulin is produced and released from beta-cells. Insulin then induces glucose uptake by cells in the body and converts glucose to glycogen in the liver. When blood glucose concentration becomes low, glycogen is broken down to glucose in the liver and glucose is released into the blood.

There are two major forms of diabetes: type 1 diabetes, also known as insulin-dependent diabetes mellitus, and type 2 diabetes, also known as non-insulin-dependent diabetes mellitus. Both types are thought to result from a reduction in the number of insulin-producing beta-cells and deficits in beta-cell function. In type 1 diabetes, beta-cells are destroyed by autoimmune responses, resulting in a lack of insulin (reviewed in Adorini *et al.*, 2002; Yoon and Jun, 2005). In type 2 diabetes, both inadequate beta-cell function and insulin resistance of peripheral tissues contribute to the development of hyperglycemia, leading to eventual reduction in the number of beta-cells (reviewed in LeRoith, 2002). Intensive exogenous insulin therapy has been used for the treatment of type 1 diabetes, but it does not restore the tight control of blood glucose levels or completely prevent the development of complications. In addition, multiple daily injections are cumbersome and sometimes cause potentially life-threatening hypoglycemia. Islet transplantation has been considered an alternative and safe method for the treatment of diabetes (reviewed in Hatipoglu *et al.*, 2005).

With the improvement of islet isolation techniques, the success rate for independence from exogenous insulin is increasing. However, the lack of sufficient islets to meet the demands of patients and the side effects of immunosuppressive drugs that are required to prevent alloimmune and autoimmune attack against islet grafts are the major limitations of islet transplantation. Therefore, various alternative sources of insulin-producing cells are being investigated to provide a sufficient supply for the treatment of type 1 diabetes.

In this chapter, we discuss the use of cell engineering to produce and expand insulin-producing beta-cells; to create insulin-producing cells from non-beta-cells, embryonic stem cells, and adult stem cells; and to improve islet graft survival. Due to the publisher's restrictions, we are unable to cite all the references for primary data.

## II. ENGINEERING TO GENERATE INSULIN-PRODUCING CELLS

### Engineering Pancreatic Beta-Cells

The pancreas is composed of endocrine and exocrine tissues. The endocrine pancreas occupies less than 5% of the pancreatic tissue mass and is composed of cell clusters called the *islets of Langerhans*. The islets of Langerhans contain insulin-producing beta-cells (about 80% of cells in the islets), glucagon-producing alpha-cells, somatostatin-producing delta-cells, and pancreatic polypeptide-producing cells. The exocrine pancreas occupies more than 95% of the pancreas and is composed of acinar and ductal cells, which produce digestive enzymes. The beta-cell mass is dynamic and increases in response to environmental changes such as pancreatic injury and physiological changes such as insulin resistance. In addition, mature beta-cells can replicate throughout life, although at a low level.

One approach to produce beta-cells for replacement therapy is to expand mature beta-cells *in vitro*. However, because mature beta-cells have limited proliferative capacity in culture, the expression of oncogenes has been tried as a method to establish beta-cell lines. The expression of simian virus (SV) 40 large T antigen in beta-cells under the control of the tet-on and tet-off regulatory system in transgenic mice resulted in a stable beta-cell line that could be expanded *in vitro*. These cells produced less insulin in the transformed state when T antigen was expressed, but insulin production increased after growth was arrested by cessation of T antigen expression, and insulin secretion was regulated as in normal mouse islets. When these cells were transplanted into streptozotocin-induced diabetic mice, the mice became normoglycemic, and normoglycemia was maintained for a prolonged time, without any treatment to prevent oncogene expression (Milo-Landesman *et al.*, 2001). In addition to beta-cell expansion, cell engineering has been used to improve beta-cell function. Rat insulinoma

cells that showed decreased glucose-responsive insulin secretion were transfected with a plasmid encoding a mutated form of GLP-1 that is resistant to the degrading enzyme dipeptidyl-peptidase IV. These engineered cells had increased insulin secretion in response to glucose, as compared with untransfected control cells (Islam *et al.*, 2005).

Expansion of human primary pancreatic islet cells has also been tried. Primary adult islet cells could be stimulated to divide when grown on an extracellular matrix in the presence of hepatocyte growth factor/scatter factor, but growth was arrested after 10–15 cell divisions, due to cellular senescence (Beattie *et al.*, 1999). Transformation of adult human pancreatic islets with a retroviral vector expressing SV40 large T antigen and H-ras<sup>Val12</sup> oncogenes resulted in extended life span, but eventually the cells entered a crisis phase followed by altered morphology, lack of proliferation, and cell death, suggesting that immortalization of human beta-cells is more difficult than that of rodent beta-cells. However, introduction of human telomerase reverse transcriptase (hTERT) resulted in successful immortalization (Halvorsen *et al.*, 1999), because human cells do not express telomerase. This immortalized cell line, βlox5, initially expressed low levels of insulin, but insulin production subsequently fell to undetectable levels as a result of the loss of expression of key insulin gene transcription factors. A combination of the introduction of a beta-cell transcription factor (Pdx-1), treatment with exendin-4 (a glucagon-like peptide-1 [GLP-1] homolog), and cell–cell contact was required to recover beta-cell differentiated function and glucose-responsive insulin production (de la Tour *et al.*, 2001). However, Pdx-1 expression in this cell line resulted in a significant decrease in the growth rate of the cells. When streptozotocin-induced diabetic animals were transplanted with these Pdx-1-expressing cells, substantial levels of circulating human C-peptide were detected and diabetes was remitted. However, 10% of the animals developed tumors, even though the oncogenes and hTERT gene had been floxed by loxP sites so that they could be deleted by expression of Cre recombinase. This suggests that the Cre-expressing adenovirus and/or Cre-mediated deletion of the oncogenes was inefficient (de la Tour *et al.*, 2001).

The limitations of previously engineered beta-cell lines point to a need for a human beta-cell line that is functionally equivalent to primary beta-cells, can be expanded indefinitely, and can be rendered nontumorigenic. In another approach to establish a reversibly immortalized human beta-cell line, human islets were transduced with a combination of retroviral vectors expressing SV40 T antigen, hTERT, and enhanced green fluorescent protein to immortalize and mark terminally differentiated pancreatic beta-cells. These genes were floxed by loxP sites to allow excision of the immortalizing genes. Among 271 clones screened for tumorigenicity, 253 clones were selected for further study, and only one of these (NAKT-15) expressed insulin and the necessary beta-cell transcription factors, such as Isl-1, Pax-

6, Nkx6.1, Pdx-1, prohormone convertases, and secretory granule proteins. Addition of factors that enhance insulin expression and secretion during culture of the beta-cell line, such as troglitazone, a peroxisome proliferator-activated receptor- $\gamma$  activator, and nicotinamide, helped to maintain the function of beta-cells, and culture of these cells on Matrigel matrix facilitated aggregate formation. Removal of the immortalizing genes by Cre recombinase expression stopped cell proliferation and increased the expression of beta-cell-specific transcription factors, resulting in reversion of the cells. These reverted NAKT-15 cells were functionally similar to normal human islets with respect to insulin secretion in response to glucose and nonglucose secretagogues, although the insulin content and amount of secreted insulin were lower than for human islets. However, NAKT-15 cells were able to remit diabetes and clear exogenous glucose when transplanted into diabetic severe combined immunodeficiency (SCID) mice. The insulin content of these cells was higher *in vivo* than *in vitro*, suggesting that the microenvironment may enhance cellular differentiation (Narushima *et al.*, 2005).

For clinical application of reversibly immortalized human beta-cells, safety issues, particularly tumorigenicity, should be considered. Reducing or eliminating tumorigenicity may be possible by using multiple selection procedures. In the case of NAKT-15 cells, nontumorigenic clones were first selected by screening for tumor formation in SCID mice. After infection of Cre-expressing adenovirus to remove the SV40 T antigen and hTERT, SV40T-negative cells were selected in the presence of a neomycin analog (the neomycin-resistance gene was positioned to be expressed after the loxP-flanked genes were deleted), and hTERT-negative cells were selected by purification of enhanced green fluorescent protein-negative cells. Finally, SV40T/hTERT-negative cells were selected by the addition of ganciclovir, because the cells had been transduced with a suicide gene, herpes simplex thymidine kinase, which renders them susceptible to ganciclovir. These multiple selection procedures resulted in no tumor development in SCID mice when reverted NAKT-15 cells were transplanted (Narushima *et al.*, 2005), although the possibility of tumorigenesis could not be completely eliminated. Nevertheless, there are advantages of reversibly immortalized human beta-cells as compared with primary beta-cells. They can be easily expanded to obtain sufficient cells for transplantation and genetically manipulated *in vitro* prior to transplantation, for example, to confer resistance to immune attack.

Establishment of insulin-producing beta-cell lines by reversible immortalization of primary islets is a promising approach for replacing insulin injections, for a beta-cell line can provide an abundant source of beta-cells for transplantation. In addition, beta-cell lines can be genetically manipulated to improve their function and survival. However, the functionality of the cell lines and safety issues remain to be further studied.

## Engineering Surrogate Beta-Cells

Non-beta-cells that are genetically engineered to produce insulin may have an advantage over intact islets or engineered beta-cells for transplantation therapy, because non-beta-cells should not be recognized by beta-cell-specific autoimmune responses. Pancreatic beta-cells have unique characteristics specific to the production of insulin, such as specific peptidases, glucose-sensing systems, and secretory granules that can release insulin promptly by exocytosis in response to extracellular glucose levels. Therefore, the ideal target cell to engineer for insulin production would be non-beta-cells possessing similar characteristics. A variety of cell types, including fibroblasts, hepatocytes, neuroendocrine cells, and muscle cells, have been engineered to produce insulin, with varying degrees of success (reviewed in Xu *et al.*, 2003; Yoon and Jun, 2002).

Neuroendocrine cells have received considerable attention because they have characteristics similar to those of beta-cells and contain components of the regulated secretory pathway, including prohormone convertases 2 and 3 and secretory granules. A mouse corticotrophic cell line derived from the anterior pituitary, AtT20, expressed active insulin after transfection with the insulin gene under the control of a viral or metallothionein promoter but lacked glucose responsiveness. Cotransfection of genes encoding glucose transporter (GLUT)2 and glucokinase conferred glucose-responsive insulin secretion in insulin-expressing AtT20 cells. Transgenic expression of insulin in the intermediate lobe of the pituitary of nonobese diabetic (NOD) mice under the control of the pro-opiomelanocortin promoter resulted in the production of biologically active insulin. Transplantation of this insulin-producing pituitary tissue into diabetic NOD mice restored normoglycemia, but insulin secretion was not properly regulated by glucose. Engineering primary rat pituitary cells to coexpress GLP-1 receptor and human insulin resulted in GLP-1-induced insulin secretion (Wu *et al.*, 2003).

Intestinal K-cells have been explored as possible surrogate beta-cells. K-cells are endocrine cells located in the gut that secrete the hormone glucose-dependent insulinotropic polypeptide (GIP), which facilitates insulin release after a meal. K-cells are also glucose responsive, have exocytotic mechanisms, and contain the necessary enzymes for processing proinsulin to insulin. A murine intestinal cell line containing K-cells transfected with human insulin DNA cloned under the control of the GIP promoter produced biologically active insulin in response to glucose, and transgenic mice expressing the human proinsulin gene under the GIP promoter were protected from diabetes after treatment with streptozotocin (Cheung *et al.*, 2000). These results suggest that K-cells may have great potential as surrogate beta-cells.

The strategy of engineering hepatocytes to produce insulin has been widely studied (Nett *et al.*, 2003). Hepatocytes have advantages for engineering as insulin-producing

cells because they express components of a glucose-sensing system somewhat similar to that in pancreatic beta-cells, such as GLUT2 and glucokinase. In addition, there are several hepatocyte-specific gene promoters that respond to changes in glucose concentrations. The L-type pyruvate kinase promoter (LPK) and Spot14 promoter have been investigated as regulatory elements for glucose-responsive insulin production in liver. Using a chimeric promoter composed of three copies of the stimulatory glucose-responsive element from the LPK promoter and an inhibitory responsive element from the insulin-like growth factor-binding protein-1 basal promoter, the expression of a modified human proinsulin gene was stimulated by glucose and inhibited by insulin in hepatocytes. Engineering of rat hepatoma cells to express insulin under the control of the glucose-6-phosphatase promoter resulted in the stimulation of insulin production by glucose and self-limitation by insulin. However, insulin expression by the glucose-6-phosphatase promoter was low because of negative feedback by the produced insulin. It was recently reported that human hepatoma cells transduced with a furin-cleavable human preproinsulin gene under the control of the GLUT2 promoter expressed insulin in response to glucose (Burkhardt *et al.*, 2005).

A drawback for the regulation of insulin production by glucose-responsive promoters in hepatocytes is slow as compared with the rapid release by exocytosis from beta-cells. Because a longer period of time is required for transcriptional regulation to change the plasma levels of insulin in response to changes in blood glucose, hypoglycemia may occur. Therefore, the development of systems that mimic insulin secretory dynamics is required. Strategies that utilize synthetic promoters composed of multiple copies of glucose-responsive elements for the induction of high levels of insulin expression, insulin-sensitive elements for feedback regulation, and methods to control of the half-life of insulin mRNA so that it rapidly degrades may make it possible to mimic insulin production in a glucose-responsive fashion in non-beta-cells.

Another consideration is that most non-beta-cells do not have the appropriate endoproteases to convert proinsulin to insulin or secretory granules from which insulin can be rapidly released in response to physiological stimuli. One approach is the mutation of the proinsulin gene so that it can be cleaved and converted to insulin by the protease furin, which is expressed in a wide variety of cells. Another approach is the development of a single-chain insulin analog, which shows insulin activity without the requirement for processing. Artificially regulated insulin secretion in non-beta-cells has been tried by expressing insulin as a fusion protein containing an aggregation domain, which accumulates in the endoplasmic reticulum and is secreted when a drug that induces disaggregation is administered.

Although engineering somatic non-beta-cells to produce insulin is a very attractive method, no method has yet

succeeded in imitating normal beta-cells regarding the rapid and tight regulation of glucose within a narrow physiological range. Improvements, including better control of glucose-responsive transcription of transgenic insulin mRNA and artificial secretory systems, provide hope for the potential use of insulin-producing non-beta-cells to cure diabetes.

## Engineering Stem and Progenitor Cells

An exciting advance in the last few years is the development of cell therapy strategies using stem cells. Stem cells are characterized by the ability to proliferate extensively and differentiate into one or more specialized cell types. Both embryonic and adult stem cells have been investigated as alternative sources for the generation of insulin-producing pancreatic islets. Although spontaneous differentiation of beta-cells from stem cells can be observed, engineering of stem cells for forced expression of key beta-cell or endocrine differentiation factors should be more efficient for driving beta-cell differentiation.

## Engineering Embryonic Stem Cells

In principle, embryonic stem (ES) cells have the potential to generate unlimited quantities of insulin-producing cells. ES cells can be expanded indefinitely in the undifferentiated state and differentiated into functional beta-cells. However, generation of fully differentiated beta-cells from ES cells has been difficult and controversial. Beta-cell differentiation from ES cells as determined on the basis of immunohistochemical evidence alone has been questioned, because insulin immunoreactivity can also result from insulin absorption from the medium as well as from genuine beta-cell differentiation. Therefore, these types of results should be interpreted with caution.

Some promising results have been reported for the differentiation of insulin-producing cells from mouse and human ES cells (reviewed in Bonner-Weir and Weir, 2005; Jun and Yoon, 2005; Montanya, 2004; Stoffel *et al.*, 2004). Pancreatic endocrine cells, including insulin-producing cells, could be generated from mouse embryonic stem cells by a five-step protocol, including the enrichment of nestin-positive cells from embryoid bodies, and these cells secreted insulin in response to glucose and other insulin secretagogues, such as tolbutamide and carbachol. However, these cells could not remit hyperglycemia when transplanted into diabetic mice. A modified protocol, in which a phosphoinositide kinase inhibitor was added to the medium to inhibit cell proliferation, resulted in improved insulin content and glucose-dependent insulin release. To enrich insulin-producing cells from mouse ES cells, a neomycin-resistance gene regulated by the insulin promoter was transferred to ES cells, which drove differentiation of insulin-secreting cells, and transplantation of these cells restored normoglycemia in streptozotocin-induced diabetic mice. In another report, mouse ES cells were transduced with a

plasmid containing the Nkx6.1 promoter gene, followed by a neomycin-resistance gene to select the Nkx6.1-positive cells, and were differentiated in the presence of exogenous differentiating factors. The selected Nkx6.1-positive cells coexpressed insulin and Pdx-1, and transplantation of these cells into streptozotocin-induced diabetic mice resulted in normoglycemia.

Exogenous expression of beta-cell transcription factors has been used as a strategy to drive the differentiation of insulin-producing cells from ES cells. Overexpression of Pax4 in mouse ES cells promoted the differentiation of nestin-positive progenitor and insulin-producing cells, and these cells secreted insulin in response to glucose and normalized blood glucose when transplanted into diabetic mice (Blyszczuk *et al.*, 2003). In the same study, the expression of Pdx-1 did not have a significant effect on the differentiation of insulin-producing cells from ES cells. However, another study demonstrated that the regulated expression of Pdx-1 in a murine ES cell line by the tet-off system enhanced the expression of insulin and other beta-cell transcription factors (Miyazaki *et al.*, 2004).

It was shown that human ES cells can spontaneously differentiate *in vitro* into insulin-producing beta-cells, evidenced by the secretion of insulin and expression of other beta-cell markers (Assady *et al.*, 2001). Differentiation of insulin-expressing cells from human ES cells was promoted when they were cultured in conditioned medium in the presence of low glucose and fibroblast growth factor, followed by nicotinamide (Segev *et al.*, 2004). A recent report suggested that human ES cells differentiated into beta-cell-like clusters when cotransplanted with mouse dorsal pancreas (Brolen *et al.*, 2005). Although several *in vitro* studies suggest the possibility of generating insulin-expressing cells from human ES cells, differentiation of truly functional beta-cells from human ES cells has not yet been reported.

Because of their proliferative ability and capacity to differentiate in culture, ES cells have received much attention as a potential source of unlimited quantities of beta-cells for transplantation therapy for diabetes. However, use of ES cells has ethical concerns, and the mechanisms by which ES cells differentiate to produce islets and beta-cells are not well understood. Therefore, further studies are needed to understand the details of the endoderm and beta-cell differentiation process so that an effective protocol for differentiating ES cells into insulin-producing cells can be developed.

### Engineering Adult Stem and Progenitor Cells

As with ES cells, adult stem cells have the potential to differentiate into other cell lineages, but they do not bring the ethical difficulties associated with ES cells. Beta-cell neogenesis in adults has been reported in animal models of experimentally induced pancreatic damage, suggesting the

presence of adult stem/progenitor cells. These adult stem/progenitor cells could be potential sources for the production of new insulin-producing cells (reviewed in Jun and Yoon, 2005; Montanya, 2004; Nir and Dor, 2005). Bone marrow, mesenchymal splenocytes, neural stem cells, liver oval stem cells, and pancreatic stem cells have been investigated for their potential to differentiate into insulin-producing cells.

A large body of evidence suggests that the adult pancreatic ducts are the main site of beta-cell progenitors. Throughout life, the islets of Langerhans turn over slowly, and new small islets are continuously generated by differentiation of ductal progenitors (Finegood *et al.*, 1995). It was found that isletlike clusters were generated *in vitro* from mouse pancreatic ducts and ductal tissue-enriched human pancreatic islets. In addition, multipotent precursor cells clonally identified from pancreatic islets and ductal populations could differentiate into cells with beta-cell function. The expression of the Pdx-1 gene or treatment of ductal cells with Pdx-1 protein increased the number of insulin-positive cells or induced insulin expression. Ectopic expression of neurogenin 3, a critical factor for the development of the endocrine pancreas in humans, in pancreatic ductal cells led to their conversion into insulin-expressing cells. In addition, treatment of human islets containing both ductal and acinar cells with a combination of epidermal growth factor and gastrin induced neogenesis of islet beta-cells from the ducts and increased the functional beta-cell mass. In addition to ductal cells, exocrine acinar cells and other endocrine cells can generate beta-cells. An alpha-cell line transfected with Pdx-1 expressed insulin when treated with betacellulin. It was shown that treatment of rat exocrine pancreatic cells with epidermal growth factor and leukemia inhibitory factor could induce differentiation into insulin-producing beta-cells (Baeyens *et al.*, 2005). Considerable evidence suggests that beta-cells in the pancreatic islets can be dedifferentiated, expanded, and redifferentiated into beta-cells by inducing the epithelial-mesenchymal transition process (Lechner *et al.*, 2005). Nonendocrine pancreatic epithelial cells also have been reported to differentiate into beta-cells (Hao *et al.*, 2006). These results suggest that pancreatic stem/progenitor cells are the source of new islets.

There is also the possibility of manipulating stem/progenitor cells from other organs to transform into the beta-cell phenotype (reviewed in Montanya, 2004; Nir and Dor, 2005). Although there are controversies regarding the differentiation of bone marrow-derived stem cells into insulin-producing cells, some successful studies have been reported. *In vitro* differentiation of mouse bone marrow cells resulted in the expression of genes related to pancreatic beta-cell development and function. These differentiated cells released insulin in response to glucose and reversed hyperglycemia when transplanted into diabetic mice. In addition, ectopic expression of key transcription factors of the endocrine

pancreas developmental pathway, such as IPF1, HLXB9, and FOXA2, in combination with conditioned media in human bone marrow mesenchymal stem cells differentiated them into insulin-expressing cells (Moriscot *et al.*, 2005).

Because the liver and intestinal epithelium are derived from gut endoderm, as is the pancreas, the generation of islets from both developing and adult liver and intestinal cells has been tried. Rat hepatic oval stem cells could differentiate into insulin-producing isletlike cells when cultured in a high-glucose environment. Fetal human liver progenitor cells and mouse hepatocytes could differentiate into insulin-producing cells when engineered to produce Pdx-1, and transplantation of these cells reversed hyperglycemia in mice. It was reported that adult human liver cells engineered to express Pdx-1 produced insulin and secreted it in a glucose-regulated manner. Transplantation of these engineered cells under the renal capsule of diabetic mice resulted in prolonged reduction of hyperglycemia (Sapir *et al.*, 2005). As well, ectopic islet neogenesis in the liver could be induced by gene therapy with a combination of NeuroD, a transcription factor downstream of Pdx-1, and betacellulin, which reversed diabetes in streptozotocin-treated diabetic mice. Expression of Pdx-1 in a rat enterocyte cell line in combination with betacellulin treatment or coexpression of Isl-1 resulted in the expression of insulin. Treatment of developing as well as adult mouse intestinal cells with GLP-1 induced insulin production, and transplantation of these cells into streptozotocin-induced diabetic mice remitted diabetes. A recent study showed that neural progenitor cells could generate glucose-responsive, insulin-producing cells when exposed *in vitro* to a series of signals for pancreatic islet development (Hori *et al.*, 2005). These results suggest that the controlled differentiation of liver or intestinal cells into insulin-producing cells may provide an alternative source of beta-cells.

The use of adult stem/progenitor cells for generating beta-cells for transplantation therapy appears to be promising, although most of the studies have only been done in animal models. Further studies on the mechanisms for the differentiation of adult stem/progenitor cells into insulin-producing beta-cells and the characterization of the newly generated beta-cells are required before these cells can be considered for clinical application.

### III. ENGINEERING TO IMPROVE ISLET SURVIVAL

A hurdle to overcome for islet transplantation therapy is the rejection and autoimmune attack against the transplanted beta-cells. Immunosuppressive drugs have been used successfully, but they have many side effects. Therefore, it is desirable to develop drug-free strategies for the induction of tolerance to transplanted islet or beta-cells. A variety of approaches to protect islet grafts have been studied, such as bone marrow transplantation, treatment

with anti-T-cell agents, and inhibition of activation of antigen-presenting cells. Another approach is engineering islets or beta-cells to express therapeutic genes to improve islet viability and function, such as genes for cytokines, antiapoptotic molecules, antioxidants, immunoregulatory molecules, and growth factors (reviewed in Giannoukakis and Trucco, 2005; Jun and Yoon, 2005; Van Linthout and Madeddu, 2005) (Table 43.1).

With regard to cytokines, introduction of genes for interleukin (IL)-4 or a combination of IL-10 and transforming growth factor- $\beta$  improved islet graft survival by preventing immune attack in mice. In addition, islets expressing the p40 subunit of IL-12 could maintain normoglycemia when transplanted into diabetic NOD recipients by decreasing interferon- $\gamma$  production and increasing transforming growth

**Table 43.1. Engineering islets for beta-cell survival**

Strategy	Molecules used
Cytokine expression	Erythropoietin
	Interleukin (IL)-1 receptor antagonist
	IL-4
	IL-10
	IL-12p40
Antiapoptotic molecule expression	Transforming growth factor- $\beta$
	A20
	Bcl-2
	Bcl-xL
	Dominant-negative MyD88
	Fas ligand
	Flice-like inhibitory protein
	I $\kappa$ B kinase inhibitor
	Tumor necrosis factor receptor-immunoglobulin (Ig)
	Catalase
Antioxidant molecule expression	c-Jun N-terminal kinase inhibitory peptide
	Glutathione peroxidase
	Heme oxygenase-1
	Manganese superoxide dismutase
	Adenoviral E3 genes
	CD40-Ig
Immunoregulatory molecule expression	Cytotoxic T-lymphocyte antigen-4-Ig
	Dipeptide boronic acid
	Indoleamine 2,3-dioxygenase
	Hepatocyte growth factor
Growth factor expression	Insulinlike growth factor-1
	Vascular endothelial growth factor

factor- $\beta$  at the transplantation site. Islets engineered to produce IL-1 $\beta$  receptor antagonist were also found to be more resistant to rejection. Adenoviral-mediated gene transfer of erythropoietin, a cytokine that promotes survival, in islets resulted in protection of islets from apoptosis in culture and destruction *in vivo*.

Expression of antiapoptotic molecules such as Bcl-2, Bcl-xL, and A20, which inhibit nuclear factor- $\kappa$ B activation, or an I $\kappa$ B kinase inhibitor was shown to protect from apoptosis. In addition, the expression of soluble human Fas ligand, dominant negative MyD88, fllice-like inhibitory protein, or tumor necrosis factor receptor-immunoglobulin (Ig) improved allogeneic islet graft survival. A recent study demonstrated that silencing Fas expression with small interfering RNA in mouse insulinoma cells inhibited Fas-mediated beta-cell apoptosis (Burkhardt *et al.*, 2006).

Pancreatic islets are sensitive to oxidative stress because they produce relatively low amounts of antioxidant enzymes. Thus, expression of antioxidant molecules such as catalase, glutathione peroxidase, and manganese superoxide dismutase in islets or insulinoma cells could protect against oxidative stress and cytokine-induced damage. In addition, expression of heme oxygenase in pancreatic islets protected against IL-1 $\beta$ -induced islet damage. It was also found that delivery of a c-Jun-terminal kinase inhibitory peptide into isolated islets by the protein transduction system prevented apoptosis (Noguchi *et al.*, 2005).

Expression of immunoregulatory molecules that affect T-cell activation and proliferation have been tried. Expression in islets of cytotoxic T-lymphocyte antigen-4-immunoglobulin, which down-regulates T-cell activation, or CD40-Ig, which blocks CD40-CD40 ligand interactions, prolonged allogeneic and xenogeneic graft survival. Transplantation of islets overexpressing indoleamine 2,3-dioxygenase prolonged survival in NOD/SCID mice after adoptive transfer of diabetogenic T-cells, probably by inhibiting T-cell proliferation by the depletion of tryptophan at the transplantation site. Similarly, a proteasome inhibitor, dipeptide boronic acid, was found to prevent islet allograft rejection by suppressing the proliferation of T-cells. Expression of adenoviral E3 transgenes in beta-cells was found to prevent islet destruction by autoimmune attack through the inhibition of major histocompatibility complex I expression.

With regard to growth factors, adenoviral-mediated transfer of hepatocyte growth factor resulted in an improved islet transplant outcome in animal models. As well, expression of insulinlike growth factor-1 in human islets prevented IL-1 $\beta$ -induced beta-cell dysfunction and apoptosis. Insufficient revascularization of transplanted islets can deprive them of oxygen and nutrients, contributing to graft failure. Therefore the expression of vascular endothelial growth factor, a key angiogenic molecule, enhanced islet revascularization and improved the long-term survival of murine islets after transplantation into the renal capsule of diabetic mice.

Another strategy to protect islets from immune attack is microencapsulation of islets within synthetic polymers (Kizilel *et al.*, 2005). Encapsulation of islets within a semi-permeable membrane, such as alginate-poly-L-lysine-alginate, blocks the passage of larger cells but allows the passage of small molecules, thus conferring protection from autoimmune attack. However, this method has limitations for the long-term survival of islets within the microcapsules because of the lack of biocompatibility, ischemia, and limited protection from cytokine-induced damage. To overcome these limitations, a bioartificial pancreas has been developed, in which blood flows through artificial vessels in close proximity to insulin-producing cells.

A variety of approaches for engineering islets or beta-cells for improved islet graft survival and escape from immune rejection have been successful in animal models. However, the efficacy of these approaches in human diabetic patients remains to be determined.

## IV. VECTORS FOR ENGINEERING ISLETS AND BETA-CELLS

The cells of the pancreas divide very slowly; therefore gene transfer vehicles that can transduce quiescent cells have been used for the delivery of transgenes, such as nonviral plasmids and vectors based on lentivirus, adenovirus, helper-dependent adenovirus, adeno-associated virus (AAV), and herpes simplex virus. In addition, protein transduction using the cell penetrating peptide from HIV-1 transacting protein (reviewed in Becker-Hapak *et al.*, 2001) has been successfully used to engineer islets (Table 43.2). However, the choice of vector needs to be carefully made so that the vector itself does not affect islet function or viability.

Nonviral methods are considered safe, cost effective, and simple to use and do not induce an immune response, but they generally have a lower gene transfer efficacy as compared to viral-mediated gene transfer (reviewed in Nishikawa and Huang, 2001). Nonviral methods for transferring genetic material include the direct injection of DNA, either naked or enclosed in a liposome, electroporation, and the gene gun method. Cationic lipid and polymer-based plasmid delivery has been used to transduce islets, and the expression of cytotoxic T-lymphocyte antigen-4 by biolistically transfected islets improved graft survival.

Viral vectors (reviewed in Walther and Stein, 2000) have been widely used as a method of gene transfer to engineer islets and beta-cell surrogates. Retroviral vectors derived from Moloney murine leukemia virus can carry a gene efficiently and integrate it in a stable manner within the host chromosomal DNA, facilitating long-term expression of the gene. For immortalization of human islets, retroviral vectors expressing oncogenes or telomerase genes have been used (Narushima *et al.*, 2005). Although most retroviral vectors

**Table 43.2.** Vectors used for islet and beta-cell engineering

Vector	Advantages	Disadvantages
Nonviral plasmid vectors	Easy to produce	Low transduction efficiency
Retrovirus	Less toxic compared with viral vectors Long-term expression No expression of viral protein	Transient expression Only infects dividing cells Limited insertion capacity (8 Kb) Random integration into host chromosomal DNA
Lentivirus	Stable, long-term expression Infects dividing and nondividing cells Nonimmunogenic	Produces low titers of virus Limited insertion capacity (8 Kb) Random integration into host chromosomal DNA
Adenovirus	Produces high titers of virus High transduction efficiency Infects dividing and nondividing cells	Toxic Host immune response to viral proteins Short-term expression
Gutless adenovirus	Reduced toxicity and prolonged expression compared with adenoviral vector Large insertion capacity	Helper-virus contamination
Adeno-associated virus	Low immunogenicity, probably nonpathogenic Broad host range Long-term expression Infects dividing and nondividing cells	Produces low titers of virus Low transduction efficiency Limited insertion capacity (4.8 Kb)
Herpesvirus	Broad host range High insertion capacity	Toxic Induces host immune response
Protein transduction	No immunogenicity Transduces many cell types	Short half-life

only infect proliferating cells, the lentivirus genus of retroviruses, which includes the human immunodeficiency virus, has all the advantages of Moloney murine leukemia virus–derived retroviral vectors and can infect nondividing as well as dividing cells. Lentiviral vectors have been successfully used to transduce islets with marker proteins (Okitsu *et al.*, 2003).

The adenoviral vector can harbor up to 30 Kb of foreign DNA and can transduce nondividing cells with high efficiency. In addition, a relatively high titer of virus, about  $10^{12}$  plaque-forming units/mL, can be produced. The transferred genes are not integrated into the host genome, but remain as nonreplicating extrachromosomal DNA within the nucleus. Although there is no risk of alteration in cellular genotype by insertional mutation, the duration of gene expression may be short, and a strong cellular immune response to the viral proteins and, in some cases, to the transgene may be induced. Adenoviral vectors have been widely used to transduce islets for proof-of-concept experiments *in vitro* and *in vivo*. Although adenoviral vectors are toxic because of *de novo* synthesized viral proteins, islet viability and functional characteristics were not affected

when transduced *in vitro*. However, transduction of islets with a high dose of recombinant adenovirus (500 MOI) markedly reduced glucose-stimulated insulin secretion, suggesting that an optimal dose is required to result in efficient transduction without compromising islet function. In general, adenoviral vectors result in transient transgene expression; however, long-term (20-week) expression of the transgene was observed in islets transduced with  $\beta$ -galactosidase and transplanted into syngeneic diabetic mice. It was reported that double-genetic modification of the adenovirus fiber with RGD polylysine motifs significantly reduced toxicity, inflammation, and immune responses (Contreras *et al.*, 2003).

A new generation of adenovirus vectors has been developed that are completely devoid of all viral protein–coding sequences and are therefore less immunogenic and less toxic. Although these gutless viruses require the presence of a helper virus for replication, contamination by the helper virus can be avoided by genetically engineering a conditional defect in the packaging domain of the helper virus or flanking the packaging signal with loxP expression sites and encoding Cre recombinase in the supporting cell line. In

addition, the gutless vectors are known to have a prolonged expression of the transgene. However, there is no report about islet engineering using these vectors.

AAVs are nonpathogenic, replication-defective parvoviruses that can infect both dividing and nondividing cells. AAVs generally have low immunogenicity; however, the generation of neutralizing antibodies may limit readministration. This problem can be overcome by selective capsid modification of AAV to evade recognition by preexisting antibodies or by direct administration of AAV to the target tissue. The recombinant AAV vector integrates randomly into the host chromosome or may stay in the episomal state. There is a limitation in the size of the DNA that can be inserted (a maximum of 4.8 Kb); however, larger inserts can be split over two vectors and delivered simultaneously, because AAVs tend to form concatemers, although the efficiency of transduction is often reduced (Young *et al.*, 2006). Efficient transduction of islets was achieved using a high dose of AAVs with an improved recombinant AAV purification method, which improved infectious titers and yield. Transduction of islets with AAV5 is more efficient than with AAV2, due to the low number of receptors for AAV2 on islet cells. AAV1 was found to be the most efficient serotype in transducing murine islets (Loiler *et al.*, 2003). However, it was recently demonstrated that intact human and murine islets could be efficiently transduced with a double-stranded AAV2-based vector, and the transduced murine islets showed normal glucose responsiveness and viability (Rehman *et al.*, 2005).

Herpes simplex virus type 1 (HSV-1) has also been used as a viral vector. Based on the persistence of latent herpes virus after infection, HSV-1 is attractive for its efficient infectivity in a wide range of target cells and its ability to infect both dividing and nondividing cells, including islets. Transfection of human islets with Bcl-2 protected beta-cells from cytokine-induced damage. However, the transduction may be unstable, and potential health risks of this vector remain to be determined.

Protein transduction is an emerging technology to deliver therapeutic proteins into cells as an alternative to

gene therapy. This method uses peptides that can penetrate the cell membrane, such as antennapedia peptide, the HSV VP22 protein, and human immunodeficiency virus TAT protein transduction domain. The therapeutic molecule is linked to the penetrating peptide as a fusion protein, which is then used to transduce the cell (Becker-Hapak *et al.*, 2001). The protein transduction method is not immunogenic and can transduce a variety of cell types, but it has a short half-life. Delivery of antiapoptotic proteins such as Bcl-xL or anti-oxidant enzymes such as copper-zinc superoxide dismutase and heme oxygenase by protein transduction in human and rodent islets efficiently transduced the islets and improved their viability without affecting islet function (Embury *et al.*, 2001; Mendoza *et al.*, 2005).

## V. CONCLUSION

Engineering beta-cell lines and non-beta-cells, differentiating embryonic and adult stem cells, and transdifferentiating non-beta-cells have been studied as methods to provide new beta-cells for cell therapy for diabetes. Expansion of functional beta-cells by generation of reversibly immortalized human beta-cell lines has been reported, but the techniques have not been clinically proven. Generation of insulin-producing cells from non-beta-cells is an attractive method, but it has yet to achieve tight regulation of glucose-responsive insulin secretion. Differentiation of insulin-producing cells from ES cells and adult stem/progenitor cells is also a promising alternative to produce beta-cells; however, a better understanding of the mechanisms for the differentiation of beta-cells is needed to develop a successful strategy to engineer beta-cells from stem cells. Engineering of islets and beta-cells to improve the survival of islet transplants has also been investigated. Although much progress has been made, engineered beta-cells need to be carefully analyzed for true beta-cell function and possible tumorigenicity. It is hoped that continued research on beta-cell engineering will offer a potential cure for diabetes in the future.

### I. INTRODUCTION

The thymus is the principal site of T-cell development and therefore is of central importance within the immune system: Congenital athymia results in profound immunodeficiency (Flanagan, 1966; Dodson *et al.*, 1969; J. Frank *et al.*, 1999), while perturbed thymic function can lead to autoimmunity. Although highly active in early life, the thymus undergoes premature involution, such that *de novo* T-cell development diminishes significantly with age. This has implications for immune function in the aging population and in clinical procedures such as bone marrow and solid organ transplantation, where thymic function is required for T-cell reconstitution and/or tolerance induction. Interest therefore exists in enhancing immune reconstitution through regenerative or cell therapies for boosting thymus activity *in vivo* or for providing customized *in vitro*-generated T-cell repertoires for adoptive transfer. The success of such strategies is likely to depend on a detailed knowledge of the mechanisms regulating thymus development and homeostasis. Here, we review current understanding of cellular and molecular regulation of thymus organogenesis, focusing on the epithelial component of the thymic stroma, which provides many of the specialist functions required to mediate T-cell differentiation and T-cell repertoire selection.

### II. STRUCTURE AND MORPHOLOGY OF THE THYMUS

The mature thymus is a highly dynamic cellular environment, comprising developing T-lymphocytes (thymocytes) — which make up over 95% of its cellularity — and a range of stromal elements that includes mesenchymal cells, bone marrow (BM)-derived cells, vasculature and the uniquely specialized thymic epithelium (Boyd *et al.*, 1993).

The mature thymus is encapsulated and lobulated and contains three principal histologically defined regions: the cortex, the medulla and the subcapsule (Fig. 44.1). The capsule and trabeculae consist of a thick layer of connective tissue and are separated from the cortex by a thin layer of simple epithelium, the subcapsule (Boyd *et al.*, 1993). The cortex and medulla each contain open networks of epithelial cells, which are densely packed with thymocytes (Van Vliet *et al.*, 1985; Boyd *et al.*, 1993; van Ewijk *et al.*, 1994), and each of these regions contains several different morphologically and phenotypically distinct epithelial subtypes (see later). The outer cortex also contains fibroblasts, and the organ as a whole is heavily vascularized. BM-derived stromal cells are found in both compartments, macrophages being distributed throughout the organ, while thymic dendritic

**FIG. 44.1.** Histology of the postnatal thymus. The postnatal thymus is surrounded by a capsule consisting of mesenchymal cells and connective tissue that penetrates into the thymus at regular intervals to form trabeculae. Underlying the capsule and trabeculae is the subcapsular epithelium, consisting of a layer of simple epithelium, which overlies the outer cortex. The cortex is populated with cortical thymic epithelial cells (cTEC), macrophages, and developing thymocytes at the triple negative (TN) and double positive (DP) stages of development. Thymocytes enter the thymus at the corticomedullary junction (CMJ) via the vasculature and migrate through the cortex to the subcapsule as they differentiate. The cortex can be divided into four zones based on the differentiation status of thymocytes that reside within it. Thus, zone 1 contains the most immature TN1 thymocytes and zone 4 contains thymocytes undergoing the TN4–DP transition. DP thymocytes are then screened for propensity to recognize self-MHC, a process termed *positive selection*, and those selected to mature into CD4<sup>+</sup> or CD8<sup>+</sup> single positive (SP) cells migrate into the medulla, where they undergo the final stages of maturation before being exported to the periphery. Central tolerance is established by deletion of self-reactive thymocytes in a process termed *negative selection*, and it is thought to occur principally at the corticomedullary junction and in the medulla: Negative selection is mediated by both thymic dendritic cells and medullary TECs, which supply self-peptides to medullary dendritic cells (DCs) in a process termed *cross-presentation*. Medullary TECs are also required for the generation of CD4<sup>+</sup>CD25<sup>+</sup> T regulatory (Treg) cells and natural killer T-cells, both of which actively repress self-reactive T-cells.

cells — which are required for imposition of tolerance on the emerging T-cell repertoire — are found predominantly at the corticomedullary junction and in the medulla itself (Boyd *et al.*, 1993).

Thymus structure is intimately linked to its principal function, to support T-cell development. This encompasses the linked processes of T-cell differentiation and T-cell repertoire selection, which together ensure that the peripheral T-cell repertoire is populated predominantly by T-cells that have propensity to bind antigen in the context of self-major histocompatibility antigens (MHC) but that do not bind self-peptides. T-cell development has been extensively reviewed elsewhere (Zuniga-Pflucker and Lenardo, 1996; Petrie, 2002; Rothenberg and Dionne, 2002) and is not discussed in detail herein. In brief, hematopoietic progenitors enter the postnatal thymus at the corticomedullary junction, and subsequent T-cell development is then regulated such that thymocytes at different stages of development are found in different intrathymic locations. T-cell differentiation from the earliest postcolonization stages of thymocyte

maturation [termed *triple negative* (TN) cells because they do not express CD3 or the coreceptors CD4 and CD8] through to the CD4<sup>+</sup>CD8<sup>+</sup> double positive (DP) stage occurs in the cortex, and the cortex itself can be subdivided into four regions based on the localization of different thymocyte populations. Thus, zone 1 contains the colonizing population of hematopoietic progenitor cells; these early thymocytes undergo proliferative expansion in zone 2; T-cell lineage commitment is completed in zone 3; and in zone 4, thymocytes differentiate to the DP stage of development, characterized by expression of both CD4 and CD8 coreceptors (Lind *et al.*, 2001; Porritt *et al.*, 2004). DP cells are then screened for their propensity to recognize self-MHC, a process termed *positive selection*, and those selected to mature into CD4<sup>+</sup> or CD8<sup>+</sup> single positive (SP) cells migrate into the medulla (Kurobe *et al.*, 2006). Central tolerance is established by deletion of self-reactive thymocytes at the DP–SP transition, in a process termed *negative selection* (Baldwin *et al.*, 2005), and is thought to occur principally at the corticomedullary junction and in the medulla. SP

thymocytes proliferate and undergo the final stages of T-cell maturation in the medulla before exiting into the peripheral immune system. The outward migration of thymocytes, from the corticomedullary junction to the outer cortex, is regulated by chemokines (Plotkin *et al.*, 2003), as is the migration of positively selected cells from the cortex into the medulla (Ueno *et al.*, 2004; Kurobe *et al.*, 2006).

### Thymic Epithelial Cells

The thymic epithelium (TE) can be usefully classified into three broad subtypes: subcapsular/subtrabecular, cortical and medullary thymic epithelial cells. Within these subdivisions, ultrastructural and immunohistochemical analyses have revealed at least six different subsets (van de Wijngaert *et al.*, 1983), assigned as “clusters of thymic epithelial staining” (CTES) types I, II, III, IIIB, IIIC, and IV (Brekelmans and van Ewijk, 1990) based on different mAb staining profiles.

Thus, subcapsular/subtrabecular epithelium consists of type 1 epithelial cells in a simple epithelial layer. These cells are MHC Class II negative (Boyd *et al.*, 1992) and are reactive to CTES II mAbs (Godfrey *et al.*, 1990). The outermost cortical subpopulation comprises type II epithelial cells, characterized by their pale appearance in electronmicrographs (van de Wijngaert *et al.*, 1984). Immediately adjacent to the type II epithelia are type III thymic epithelial cells, which show intermediate electron lucency (van de Wijngaert *et al.*, 1984), while the innermost cTEC are type IV cells, which have high electron lucency and oval/spindle-shaped nuclei (van de Wijngaert *et al.*, 1984). Ultrastructural analysis has also revealed large complexes of type II and type III cells and developing thymocytes (van de Wijngaert *et al.*, 1984), termed *thymic nurse cells* (TNC) (Wekerle and Ketelsen, 1980a, 1980b). No mAbs are currently known to identify individual subpopulations corresponding to the types II–IV cells just described; however, all cTEC stain with CTES III mAbs (van de Wijngaert *et al.*, 1984), and types II and III cells are strongly MHC Class II positive (Boyd *et al.*, 1993). Medullary TEC (mTEC) predominantly express determinants reactive to CTES II and IV mAbs, with type III cells also identified by ultrastructural analysis (van de Wijngaert *et al.*, 1984). In addition, type V epithelia, classified as undifferentiated cells, exist in small isolated clusters at the corticomedullary junction (van de Wijngaert *et al.*, 1984), along with type VI cells, which have been proposed to be precursors of differentiated epithelial cells (von Gaudecker *et al.*, 1986). All mTEC express MHC Class I, while MHC Class II expression is variable (Jenkinson *et al.*, 1981; Farr and Nakane, 1983; Bofill *et al.*, 1985; Surh *et al.*, 1992).

The different thymic epithelial subpopulations are also defined by differential expression of cytokeratins (K). Two cortical populations have been identified: a predominant K5<sup>+</sup>K14<sup>+</sup>K8<sup>+</sup>K18<sup>+</sup> subset and a minor subset also consisting of K5<sup>+</sup>K14<sup>+</sup>K8<sup>+</sup>K18<sup>+</sup> cells (Klug *et al.*, 1998). Most mTEC display a K5<sup>+</sup>K14<sup>+</sup>K8<sup>+</sup>K18<sup>+</sup> phenotype (Klug *et al.*, 1998) and

also express the antigen reactive to mAb MTS10 (Godfrey *et al.*, 1990), and a minor K5<sup>+</sup>K14<sup>+</sup>K8<sup>+</sup>K18<sup>+</sup> MTS10<sup>+</sup> medullary subset is also present (Klug *et al.*, 1998).

While precise functions are not ascribed to all of these TEC subpopulations, the clear functional dichotomy between the cortical and medullary compartments is reflected in functional differences between the cortical and medullary thymic epithelial cell types. Notably, cortical thymic epithelial cells (cTEC) are believed to express a ligand required for positive selection (Anderson *et al.*, 1994), while a subset of medullary thymic epithelial cells (mTEC) expresses AIRE1 (AIRE1 positively regulates expression of a cohort of tissue or developmentally restricted genes that play an essential role in the induction of central tolerance) (M. S. Anderson *et al.*, 2002). This high level of phenotypic and functional heterogeneity presents a significant challenge for attempts to support full T-cell development, including proper repertoire selection *in vitro*, and is also pertinent to cell replacement or regenerative strategies for enhancing thymus activity *in vivo*.

### III. IN VITRO T-CELL DIFFERENTIATION

The ability to generate T-cells in culture is widely used as a tool for investigating the regulation of T-cell differentiation (Hare *et al.*, 1999) and is also of interest for clinical and pharmaceutical purposes. Several methodologies exist that are based on the use of *ex vivo* thymic tissue. Thus, fetal thymic organ culture (FTOC) utilizes *ex vivo* thymic lobes usually derived from E15.5–E16.5 mouse embryos or second-trimester human fetuses to support the differentiation of T-cell progenitors from endogenous or exogenous sources (Jenkinson and Owen, 1990; Yeoman *et al.*, 1993; Barcena *et al.*, 1994; Plum *et al.*, 1994; Cumano *et al.*, 1996). The technique of reaggregate fetal thymic organ culture (RFTOC), in which defined TEC subpopulations are obtained by cell purification techniques, reaggregated with fibroblasts and defined lymphocyte populations, and then cultured further *in vitro*, was developed as an extension of FTOC and has proved invaluable for assessing the role of individual stromal components during specific stages of T-cell maturation (Jenkinson *et al.*, 1992; G. Anderson *et al.*, 1994). In addition, this approach has recently been adapted for testing the potency of different fetal and adult TEC subpopulations (Bennett *et al.*, 2002; Gill *et al.*, 2002; Rossi *et al.*, 2006).

Recently, it has been demonstrated that a tantalum-coated carbon matrix can be used to generate an *in vitro* thymic organoid when seeded with *ex vivo* murine thymic stromal cells (Poznansky *et al.*, 2000). When these structures were cocultured with human CD34<sup>+</sup> haematopoietic progenitors, efficient generation of mature CD4 and CD8 SP T-cells was observed after 14 days. The T-cells generated in this system were functional, as demonstrated by their proliferative response to mitogenic stimuli, and demonstrated a diverse TCR repertoire comparable to that of peripheral blood T-cells (Poznansky *et al.*, 2000). These findings dem-

onstrate that the utilization of three-dimensional matrices in conjunction with thymic stromal cells can provide an efficient and reproducible method of *in vitro* T-cell generation. However, this approach currently relies on seeding with *ex vivo* thymus tissue and therefore is not highly scalable in its present form.

*In vitro* T-cell differentiation has also been investigated using a derivative of the BM stromal cell line OP-9, which expresses the Notch ligand Delta-like 1 (OP-9 DL-1). Recent studies demonstrate that OP-9 DL-1 monolayers can support the generation of CD4<sup>+</sup>CD8<sup>+</sup> DP thymocytes from mouse fetal liver-, adult bone marrow-, or ES cell-derived hematopoietic progenitors (Schmitt and Zuniga-Pflucker, 2002; Schmitt *et al.*, 2004). Small numbers of CD8<sup>+</sup> SP T-cells were also produced, although CD4<sup>+</sup> SP T-cells were largely absent. This system was recently shown to support T-cell development from human cord blood- and human bone marrow-derived CD34<sup>+</sup> cells (De Smedt *et al.*, 2002; La Motte-Mohs *et al.*, 2005). However, although it has been proposed that this system presents a scalable means of supporting *in vitro* T-cell differentiation (Lehar and Bevan, 2002), it remains unclear to what extent the T-cells generated on OP9-DL1 cells undergo positive and negative selection. In an interesting alternative to generation of mature T-cells, this system has recently been used as a means of expanding a CD4<sup>+</sup>CD8<sup>+</sup> DN precursor thymocyte population, which resulted in improved T-cell reconstitution after adoptive transfer of these DN cells in a mouse model of hematopoietic stem cell transplantation (Zakrzewski *et al.*, 2006). In addition, similar to RFTOC, the OP-9 DL-1 system is a powerful experimental tool for examining aspects of T-cell differentiation (Porritt *et al.*, 2004).

T-cell differentiation *in vitro* has also been achieved using preparations of cells derived from human skin in conjunction with a tantalum-coated carbon matrix (Clark *et al.*, 2005). In this system, cutaneous keratinocytes and fibroblasts were seeded onto the matrix and supplied with human CD34<sup>+</sup> hematopoietic progenitor cells. After a period of three to four weeks, CD3<sup>+</sup> T-cells were produced that exhibited functional maturity and were tolerant to self-MHC as assessed by the mixed lymphocyte reaction. Gene expression analysis demonstrated that the cells used to seed the matrix expressed transcription factors associated with TEC function, such as Foxn1, Aire, and Hoxa3, although at much lower levels than in the normal thymus. However, the efficiency of thymopoiesis in this system was low, with a relatively low number of mature T-cells generated despite the addition of a cocktail of prolymphopoietic cytokines.

## IV. THYMUS ORGANOGENESIS

### Cellular Regulation of Early Thymus Organogenesis

The thymus arises in the pharyngeal region of the developing embryo, in a common primordium with the

parathyroid gland. This common primordium develops from the third pharyngeal pouch (3PP), one of a series of bilateral outpocketings of pharyngeal endoderm, termed the *pharyngeal pouches*, which form sequentially in a rostral-to-caudal manner.

In the mouse, outgrowth of the 3PP occurs from approximately E9.0 (Gordon *et al.*, 2004). At this stage, the epithelium of the 3PP consists of a single layer of columnar epithelium surrounded by a condensing population of neural crest cells (NCC) that will eventually form the capsule (Le Lievre and Le Douarin, 1975; Jiang *et al.*, 2000). Overt thymus organogenesis is evident from between E10.5 and E11.0, at which stage the epithelium begins to proliferate, assuming a stratified organization (Itoi *et al.*, 2001). Following this, at E12.5, the primordia separate from the pharynx and begin to resolve into discrete thymus and parathyroid organs. The thymus primordium subsequently migrates to its final anatomical location at the midline, while the parathyroid primordium associates with the lateral margins of the thyroid (Manley and Capecchi, 1995, 1998). In the case of the thymus at least, this migration is active and follows the path of the carotid artery and vagus nerve (Su *et al.*, 2001).

Within the common primordium, the prospective thymus is located in the ventral domain of the third pouch and the prospective parathyroid in the dorsal aspect. Partitioning of these prospective organ domains appears to occur early in organogenesis, for the parathyroid domain is delineated by the transcription factor Gcm2 as early as E9.5. Possible mechanisms regulating the establishment/maintenance of these domains are discussed later.

The mesenchymal capsule surrounding the thymus primordium is derived from the migratory neural crest, a transient population formed between the neural tube and the surface ectoderm. In the mouse, NCC migrate into the pharyngeal region from E9. Elegant chick-quail chimera studies provided the first evidence that NCC are the source of mesenchymal cells in the thymus (Le Lievre and Le Douarin, 1975), and this was recently confirmed in the mouse by heritable genetic labeling *in vivo* (Jiang *et al.*, 2000).

Colonization of the mouse thymus with hematopoietic progenitor cells occurs around E11.5 (Owen and Ritter, 1969; Cordier and Haumont, 1980; Jotereau *et al.*, 1987). Because vascularization has not occurred by this stage, the first colonizing cells migrate through the perithymic mesenchyme into the thymic epithelium. These cells have been reported to exhibit comparatively low T-cell progenitor activity, while a second colonizing wave, which arrives between E12 and E14, appears to display much higher levels of T-cell potential upon *in vivo* transfer (Douagi *et al.*, 2000).

The epithelial cells within the thymic primordium continue to proliferate strongly after E12.5, at least partly in response to factors supplied by the mesenchymal capsule. Concomitantly, TEC differentiation commences, with the first evidence of differentiation into cortical and medullary cell types appearing by E12.5 (Bennett *et al.*, 2002). De-

velopment of the two compartments then proceeds in a lymphocyte-independent manner until E15.5 (Klug *et al.*, 2002; Jenkinson *et al.*, 2005). The expression of MHC II and MHC I on the surface of thymic epithelial cells is first detected at E13.5 and ~E16, respectively (Jenkinson *et al.*, 1981; Van Vliet *et al.*, 1984), and is followed by the appearance of CD4<sup>+</sup> and CD8<sup>+</sup> SP thymocytes at E15.5 and E17.5 (Jenkinson *et al.*, 1981; Van Vliet *et al.*, 1984). Although a functional thymus is present in neonates, the full organization of the stroma is not achieved until two to three weeks postnatally in the mouse.

### Origin of Thymic Epithelial Cells

The precise embryonic origins of the thymic epithelium were until recently a matter of long-standing controversy; conflicting hypotheses suggested that the epithelium had a dual endodermal/ectodermal origin (Cordier and Heremans, 1975; Cordier and Haumont, 1980) or derived solely from the pharyngeal endoderm (Le Douarin and Jotereau, 1975; Manley and Blackburn, 2003; Blackburn and Manley, 2004; Gordon *et al.*, 2004). However, recent work from our laboratories has provided definitive evidence for a single endodermal origin in mice (Gordon *et al.*, 2004) through histological, fate, and potency analysis of the pharyngeal region. These data demonstrated that although the 3PP endoderm and third pharyngeal cleft ectoderm make contact at E10.5, as proposed in the dual-origin hypothesis, the germ layers subsequently separate, with apoptosis occurring in the contact region. Lineage tracing of pharyngeal surface ectoderm of E10.5 mouse embryos also failed to find evidence for an ectodermal contribution to the thymic primordium, and, finally, transplantation of pharyngeal endoderm isolated from E8.5–E9.0 embryos (i.e., prior to initiation of overt thymus organogenesis) indicated that the grafted endoderm was sufficient for complete thymus organogenesis, similar to previous results obtained using chick-quail chimeras (Le Douarin and Jotereau, 1975). Thus, pharyngeal endoderm alone is sufficient for the generation of both cortical and medullary thymic epithelial compartments.

### Thymic Epithelial Progenitor Cells (TEPC)

The phenotype of TEPC has been of considerable interest. Evidence suggestive of a progenitor/stem cell activity was initially provided by analysis of a subset of human thymic epithelial tumours that were found to contain cells that could generate both cortical and medullary subpopulations. This suggested that the tumourigenic targets were epithelial progenitor/stem cells (Schluep *et al.*, 1988). In addition, ontogenic studies suggested that the early thymus primordium in both mouse and human might be characterized by coexpression of markers that later segregated to either the cortical or medullary epithelium (Lampert and Ritter, 1988). However, the first genetic indication of a TEPC phenotype was provided by a study addressing the nature of the defect in *nude* mice, which fail to develop a

functional thymus due to a single base deletion in the transcription factor Foxn1 (Blackburn *et al.*, 1996). Here, analysis of allophenic *nude*-wild-type aggregation chimeras demonstrated that cells homozygous for the *nude* mutation were unable to contribute to the major thymic epithelial subsets, establishing that the *nude* gene product (Foxn1) is required cell-autonomously for the development and/or maintenance of all mature TEC. However, a few *nude*-derived cells were present in the thymi of adult chimeras, and phenotypic analysis indicated that these cells expressed determinants reactive to mAbs MTS20 (Godfrey *et al.*, 1990) and MTS24 but did not express markers associated with mature TEC, including MHC Class II. Based on these findings, we suggested that in the absence of Foxn1, TEC lineage cells undergo maturational arrest and persist as MTS20<sup>+</sup>24<sup>+</sup> progenitors (Blackburn *et al.*, 1996). This hypothesis was recently confirmed by an elegant study that demonstrated that functional thymus tissue containing organized cortical and medullary regions is generated on reactivation of a conditional null allele of Foxn1 in the postnatal thymus (Bleul *et al.*, 2006). Since clonal reactivation of Foxn1 was achieved in this study, it demonstrates unequivocally that in the absence of Foxn1, some persisting TECs have bipotent progenitor activity.

Further data regarding the phenotype of thymic epithelial progenitors came from analysis of mice, with a secondary block in thymus development resulting from a primary T-cell differentiation defect. The thymi of postnatal *CD3e26tg* mice, in which thymocyte development is blocked at the CD44<sup>+</sup>CD25<sup>−</sup> TN1 stage (Hollander *et al.*, 1995), contain principally epithelial cells that coexpress K5 and K8 (Klug *et al.*, 1998) — which, in the normal postnatal thymus, are predominantly restricted to the medulla and cortex respectively and are coexpressed by only a small population of cells at the corticomedullary junction. In this study, Klug and colleagues (1998) demonstrated that transplantation of *CD3e26tg* thymi into *Rag1*<sup>−/−</sup> mice, which sustain a later block in T-cell differentiation, resulted in the development of K5<sup>+</sup>K8<sup>+</sup> cells, suggesting that the K5<sup>+</sup>K8<sup>+</sup> cells are progenitors of cTEC.

More recently, two studies have addressed the phenotypic and functional properties of MTS20<sup>+</sup>24<sup>+</sup> cells within the fetal mouse thymus directly. Ontogenic analysis has demonstrated that the proportion of MTS20<sup>+</sup>24<sup>+</sup> epithelial cells was highest in the early thymus primordium, decreasing to less than 1% in the postnatal thymus (Bennett *et al.*, 2002), consistent with the expression profile expected of markers of fetal tissue progenitor cells. Phenotypic analysis of the MTS20<sup>+</sup>24<sup>+</sup> and MTS20<sup>−</sup>24<sup>−</sup> populations of the E12.5 thymus indicated that all cells in the MTS20<sup>+</sup>24<sup>+</sup> population coexpressed K5 and K8, while none expressed TEC differentiation markers, including MHC II (Bennett *et al.*, 2002). Importantly, the functional capacity of isolated MTS20<sup>+</sup>24<sup>+</sup> cells and MTS20<sup>−</sup>24<sup>−</sup> cells was then determined via ectopic transplantation. This analysis demonstrated that

the MTS20<sup>+</sup>24<sup>+</sup> population was sufficient for establishment of a functional thymus containing both cortical and medullary TEC populations, while, in this assay, the MTS20<sup>+</sup>24<sup>+</sup> population fulfilled none of these functions (Bennett *et al.*, 2002; Gill *et al.*, 2002). The studies described earlier clearly demonstrated that progenitor activity resided in the MTS20<sup>+</sup>24<sup>+</sup> population. However, although these data strongly suggested the existence of common thymic epithelial progenitor cells, this was not addressed at the clonal level in either study.

With regard to this issue, a recent study indicates that during initial organogenesis a bipotent progenitor exists that can form both cortical and medullary TECs and suggests that this activity may persist in the postnatal thymus (Bleul *et al.*, 2006). The approach used was to perform a lineage trace using hK14<sup>CreERT2</sup> transgenic mice crossed onto a ROSA26/silent eYFP background. In this system, spontaneous Cre recombinase activity in thymic epithelial cells activated the expression of eYFP in a small number of TECs at around 14 days postpartum. Analysis of the thymi by fluorescence microscopy revealed that the majority of eYFP<sup>+</sup> cells were present in clusters and were not evenly distributed throughout the stroma, suggesting that fluorescent cells were derived from a single recombination event in cells with proliferative capacity. The location of the cell clusters was mixed; a small proportion of eYFP<sup>+</sup> clusters were restricted to either the cortex or the medulla, but the majority (76%) appeared to span the corticomedullary junction. These results are consistent with the presence of a bipotent progenitor that may give rise to intermediate progenitors committed to either the cortical or medullary lineage. However, a major caveat for this interpretation is that stem cell activity per se was not assayed in these experiments and that the data would also be consistent with proliferation of differentiated epithelial cells. In an elegant extension of these experiments, the same hK14<sup>CreERT2</sup> deleter strain was used to reactivate a conditional null allele of *Foxn1* in postnatal mice (discussed earlier). Here, clonal activation of *Foxn1* resulted in the generation of small regions of thymus tissue that contained both cortical and medullary TEC, providing conclusive evidence for the existence of a common progenitor in initial organogenesis.

### Human Thymus Development

Early human thymus development closely parallels that of the mouse. Thus, the thymus forms from the third pharyngeal pouch in a common primordium with the parathyroid gland. The third pharyngeal pouch is evident from early in week 6 of human fetal development, and initially it develops as a tubelike lateral expansion from the pharynx, which makes contact with the ectoderm of the third pharyngeal cleft (Weller, 1933; Norris, 1938). A single endodermal origin has not been demonstrated directly for the human thymic epithelium. However, since the thymus has a single endodermal origin in mice and avians (Le Douarin and Jotereau,

1975), it is reasonable to assume that this is also the case in humans. Within the human common thymus/parathyroid primordia, the thymus and parathyroid domains are located ventrally and dorsally and are surrounded by condensing neural crest–derived mesenchyme from the onset of development. The thymus component of this primordium begins to migrate ventrally from week 7 to mid-week 8, forming a highly lobulated, elongated, cordlike structure. The upper part of this structure normally disappears at separation of the two organ rudiments, leaving the parathyroid in the approximate location in which it will remain throughout adulthood (Norris, 1938). The bilateral thymic primordia continue to migrate toward the midline, where they eventually meet and attach at the pericardium — the permanent location of the thymus into adulthood — by mid-week 8 (Norris, 1938). As in the mouse, the human early thymus primordium appears to contain undifferentiated epithelial cells (Bennett *et al.*, 2002), which express some markers that are later restricted to either cortical or medullary compartments (Lampert and Ritter, 1988; A. Farley and CCB, unpublished data). Nascent medullary development is evident from week 8, and by week 16 distinct cortical and medullary compartments are present. Other cell types penetrate the thymus from week 8, including mesenchymal, vascular and lymphoid cells, and mature lymphocytes begin to leave the thymus to seed the peripheral immune tissues between weeks 14 and 16 (van Dyke, 1941; Lobach and Haynes, 1986).

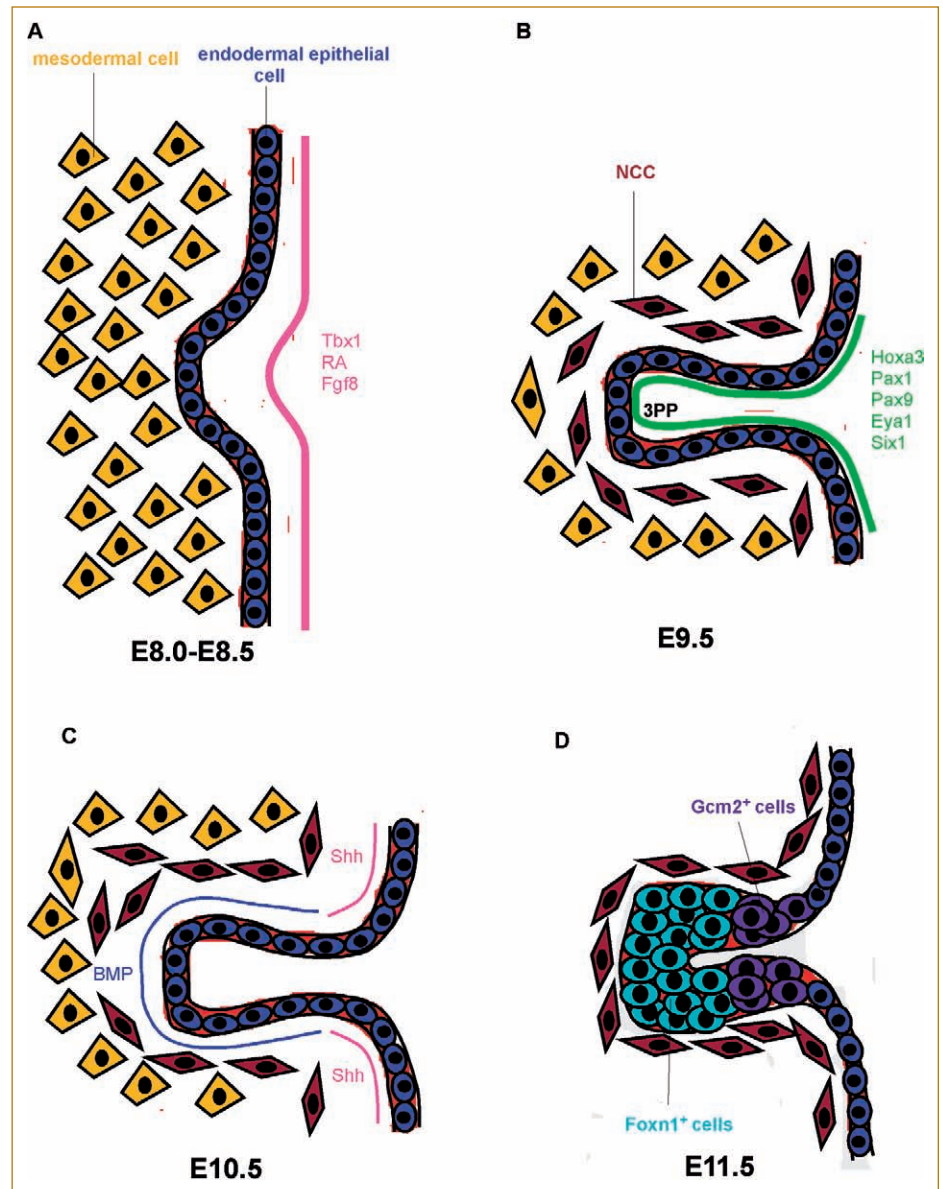

### Cervical Thymus in Mouse and Human

The presence of a cervical thymus in humans has been recorded for some time (van Dyke, 1941; Tovi and Mares, 1978; Ashour, 1995), and recent publications indicate that an ectopic cervical thymus is also a common occurrence in at least some mouse strains (Dooley *et al.*, 2006; Terszowski *et al.*, 2006). In terms of size and cellularity, the cervical thymus is much smaller than the thoracic thymus. However, the morphology of the two structures is very similar, with organized cortical and medullary regions and similar expression patterns of cytokeratin molecules (Dooley *et al.*, 2006; Terszowski *et al.*, 2006). Furthermore, the cervical thymus expresses the transcription factors *Foxn1* and *Aire* and can produce functional T-cells that are tolerant to self-antigens (Dooley *et al.*, 2006; Terszowski *et al.*, 2006).

The origin of the cervical thymus is at present unclear. A plausible hypothesis is that it may arise from remnants of the thymus domain of the 3PP that become detached from the organ during separation of the thymus and parathyroid domains. Several alternative explanations exist, and the identification of cervical thymi in mice will allow the embryonic origins of these structures to be addressed experimentally. It appears that in mice the cervical thymus may mature postnatally (Terszowski *et al.*, 2006), while in humans it is clearly present in the second trimester of fetal development. Although the presence of *Foxn1*<sup>+</sup> epithelial cells has not

**FIG. 44.2.** Molecular regulation of early thymus organogenesis. **(A)** At approximately E8.0–E8.5 the formation of the third pharyngeal pouch (3PP) is initiated in the pharyngeal endoderm and is dependent on the expression of *Tbx1* and retinoic acid (RA) and fibroblast growth factor 8 (*Fgf8*) signaling (pink). **(B)** At E9.5 the 3PP has formed and is surrounded by mesenchymal cells of mesodermal and neural crest cell (NCC) origin. Continued development is dependent on the expression of the transcription factors *Hoxa3*, *Pax1*, *Pax9*, *Eya1*, and *Six1* (green). **(C)** Bone morphogenetic protein (BMP) (blue) and sonic hedgehog (Shh) (pink) signaling occur at E10.5 in the 3PP endoderm in the ventral and dorsal aspects, respectively. These factors may be involved in the specification of the 3PP into thymus- and parathyroid-specific domains. **(D)** At E11.5 epithelial cells in the ventral domain of the 3PP express the transcription factor *Foxn1* (light blue) and will form the thymic epithelium. Epithelial cells in the dorsal domain express the transcription factor *Gcm2* (purple) and will form the parathyroid gland. The differentiation and maintenance of both of these cell types are dependent on these factors.

been reported in the cervical regions of developing mouse embryos, because it is now clear that cells specified to the thymic epithelial lineage retain their identity in the absence of *Foxn1* expression (Bleul *et al.*, 2006), *Foxn1* may not be an appropriate lineage marker for tracing the origins of this tissue.

### Molecular Regulation of Thymus and Parathyroid Organogenesis

Although the regulation of thymus organogenesis is incompletely understood, studies of classical and genetically engineered mouse mutants have begun to reveal a network of transcription factors and signaling molecules that act in the pharyngeal endoderm and surrounding mesenchyme and mesoderm to regulate thymus and

parathyroid organogenesis. The principal components of this network are discussed next and are summarized in Fig. 44.2.

### Molecular Control of Early Organogenesis

The earliest events in thymus organogenesis occur prior to overt organ development and relate to molecular control of 3PP formation. The T-box transcription factor *Tbx1*, retinoic acid (RA) signaling, and fibroblast growth factor 8 (*Fgf8*) signaling have been implicated as important regulators of this process.

*Tbx1* was recently identified as the gene responsible for cardiovascular and glandular defects in *Df1* mice, which carry a large deletion of chromosome 16 (Lindsay *et al.*, 1999). *Df1* heterozygotes closely phenocopy a human

condition known as 22q11.2 deletion syndrome (22q11.2DS, or DiGeorge Syndrome), in which a deletion in chromosome 22 covering an interval of approximately 30 genes (Scambler, 2000) results in a range of defects including thymus aplasia or, more frequently, hypoplasia (Paylor *et al.*, 2001; Taddei, Morishima *et al.*, 2001). Thus the Df1 mouse represents a useful model for 22q11.2DS and has allowed the identification of Tbx1 as a critical early regulator of pharyngeal development.

During development, Tbx1 is expressed in the pharyngeal endoderm and the core mesenchyme of the pharyngeal arches from approximately E7.5 and continues to be expressed in a variety of structures until E12.5 (Chapman *et al.*, 1996; Hu *et al.*, 2004; Xu *et al.*, 2004). Tbx1 mutants have severe defects in the pharyngeal region, including abnormal patterning of the first pharyngeal arch; hypoplasia of the second arch; and absence of the third, fourth and sixth arches and pouches (Jerome and Papaioannou, 2001). As a result of this, Tbx1<sup>-/-</sup> mutants lack both thymus and parathyroid and display a spectrum of cardiovascular abnormalities and craniofacial defects (Jerome and Papaioannou, 2001). The phenotype of Tbx1<sup>-/-</sup> animals suggests an important role for this gene in the segmentation of the pharyngeal region. Supporting evidence for this hypothesis was provided by an elegant study addressing the temporal requirement for Tbx1 in the development of the pharyngeal region. Deletion of Tbx1 at E8.5, during the formation of the 3PP, resulted in complete absence of thymus and parathyroid, and complementary fate-mapping experiments demonstrated that cells that express Tbx1 at E8.5 contribute significantly to the thymic primordium (Xu *et al.*, 2005). However, although deletion of Tbx1 at E9.5/E10.5 (after initial formation of the 3PP) caused morphological defects in the thymus, these were not as severe as the aplasia seen after deletion at E8.5, and fate mapping of cells expressing Tbx1 cells at E9.5/E10.5 revealed only a small contribution to the thymus (Xu *et al.*, 2005). Taken together, these data suggest that Tbx1 is required for establishment of the 3PP but that it is not directly required for subsequent thymus development. Thus, Tbx1 may influence later stages of thymus organogenesis in a non-cell-autonomous manner. Furthermore, although Tbx1 is haplo-insufficient with respect to thymus development (Lindsay *et al.*, 2001), the basis of this insufficiency remains to be determined and may result either from secondary effects resulting from mild defects in pouch formation or from dosage effects related to factor provision by non-NCC mesenchymal cells.

A role for RA in 3PP formation was suggested by experiments in which RA antagonist was administered to whole-embryo cultures. Here, blockade of RA signaling at E8.0 resulted in the absence of the growth factors Fgf8 and Fgf3 in the 3PP endoderm and impaired NCC migration to the third and fourth pharyngeal arches (Wendling *et al.*, 2000). Expression of the transcription factor Pax9 (see later) was also absent in the third pouch, but was expanded in the

second pouch endoderm. These data suggest that RA signaling is required for the specification of the third pouch endoderm, which confers subsequent competence to support NCC migration. *In vivo* evidence for a role for RA signaling was subsequently provided by the finding that fetal mice lacking RA receptors  $\alpha$  and  $\beta$  display thymus agenesis and ectopia (Ghyselinck *et al.*, 1997).

There is considerable evidence that Fgf8 is required during the early stages of thymus and parathyroid development. Fgf8 is expressed in the early gut endoderm and in the endoderm and ectoderm of the pharyngeal pouches and clefts. Mice carrying hypomorphic alleles of Fgf8 show defects in thymus development ranging from hypoplasia to complete aplasia (Abu-Issa *et al.*, 2002; D. U. Frank *et al.*, 2002). The initial impairment in thymus and parathyroid organogenesis is likely to occur at an early stage in development in these mice, because the third and fourth pharyngeal arches and pouches are usually hypoplastic/aplastic, in addition to other abnormalities in the pharyngeal region (Abu-Issa *et al.*, 2002; D. U. Frank *et al.*, 2002).

In terms of the cell types affected by impaired Fgf8 signaling, similarities between the phenotype of Fgf8 hypomorphs and the spectrum of abnormalities found during experimental NCC ablation (Bockman and Kirby, 1984; Conway *et al.*, 1997) suggest that the glandular defects may result from defective NCC migration/differentiation or survival. In support of this, NCC of Fgf8 hypomorphs show increased levels of apoptosis (Abu-Issa *et al.*, 2002; D. U. Frank *et al.*, 2002) and reduced expression of Fgf10 (Frank *et al.*, 2002), a factor that may mediate proliferation of the pharyngeal endoderm (D. U. Frank *et al.*, 2002). There is also a mild reduction in the expression of genes associated with differentiated NCC (Abu-Issa *et al.*, 2002), suggesting that the maintenance of NCC is perturbed. Taken together, these data implicate Fgf8 in maintaining a competent NCC population that can contribute to thymus organogenesis. However, Fgf8 may also act specifically on the 3PP endoderm, since ablation of Fgf8 in the endoderm and ectoderm or ectoderm alone results in different phenotypes; ablation in the ectoderm alone causes vascular and craniofacial defects seen in Fgf8 hypomorphs (Macatee *et al.*, 2003), whereas when Fgf8 is also deleted in the endoderm, glandular defects are evident, including thymus hypoplasia and ectopia (Macatee *et al.*, 2003). Since the NCC defects were the same in both cases, Fgf8 may directly influence development of the endoderm, although it remains possible that the differences observed result from a dosage effect.

### Transcription Factors and Regulation of 3PP Development

After the initial onset of 3PP formation, continued development is dependent on several transcription factors, most notably Hoxa3, Pax1, Pax 9, Eya1, Six1, and Six4. All of these transcription factors are expressed in the 3PP endoderm from approximately E9.5 to E10.5 and, with the excep-

tion of Pax1 and Pax9, are also expressed in associated NCC and the ectoderm.

Absence of functional Hoxa3 or Eya1 results in the failure to initiate overt thymus and parathyroid organogenesis once the 3PP has formed, revealing the essential roles of these factors (Manley and Capecchi, 1995, 1998; Xu *et al.*, 2002; Zou *et al.*, 2006). Tbx1 and Fgf8 are both down-regulated in the 3PP of Eya1<sup>-/-</sup> mice at E9.5 (Zou *et al.*, 2006), indicating that Eya1 plays a role in the regulation of each of these factors. Lack of Six1, Six1 and 4, Pax1, or Pax9 causes much less severe phenotypes. The common primordium begins to develop in Six1<sup>-/-</sup> mice, and patterning into thymus and parathyroid domains (see the next section) is initiated. However, subsequent apoptosis of endodermally derived cells in the common primordium leads to complete disappearance of the organ rudiment by E12.5 (Zou *et al.*, 2006). A similar phenotype is evident in Six1<sup>-/-</sup>;Six4<sup>-/-</sup> embryos, though the size of the primordium is further diminished in the double mutants, indicating synergy between these gene products (Zou *et al.*, 2006). Loss of function mutations in Pax9 results in failure of the primordia to migrate to the mediastinum and in severe hypoplasia from E14.5. However, the thymic lobes are vascularized and contain lymphocytes (Hetzer-Egger *et al.*, 2002). Pax1<sup>-/-</sup> mutants show relatively mild thymus hypoplasia and aberrant TEC differentiation (Wallin *et al.*, 1996; Su and Manley, 2000; Su *et al.*, 2001). Since Pax1 and 9 are highly homologous, these phenotypes may reflect functional redundancy, as demonstrated in other tissues (Peters and Balling, 1999).

Expression of Hoxa3, Eya1 and Six1 in multiple germ layers complicates interpretation of the respective null phenotypes for these genes. However, Hoxa3 appears to regulate Pax1 and Pax9 either directly or indirectly, since Pax1 and Pax9 expression is initiated normally in Hoxa3<sup>-/-</sup> mutants but fails to be maintained at wild-type levels beyond E10.5 (Manley and Capecchi, 1995). Furthermore, Hoxa3<sup>+/-</sup>;Pax1<sup>-/-</sup> compound mutants show delayed separation of the thymus/parathyroid primordium from the pharynx, resulting in thymic ectopia and a more severe hypoplasia than that seen in Pax1<sup>-/-</sup> single mutants (Su *et al.*, 2001).

It has been suggested that Eya1 and Six1 act downstream of the Hox/Pax genes, for Eya1<sup>-/-</sup> embryos show normal expression of Hoxa3, Pax1, and Pax9 but reduced expression of Six1 in the endoderm of the third and fourth pouches and ectoderm of the second, third, and fourth pharyngeal arches (Xu *et al.*, 2002). However, while it is likely that Six1 acts downstream of Eya1, recent evidence indicates that Eya1 and Six1 do not act downstream of the Pax genes. This has been shown by analysis of Pax9<sup>-/-</sup> and Pax1<sup>-/-</sup>Pax9<sup>-/-</sup> mutants, which show normal expression of Eya1 and Six1 in the 3PP, and of Eya1<sup>-/-</sup>;Six1<sup>-/-</sup> double mutants, which lack expression of Pax1 in the E10.5 3PP (Zou *et al.*, 2006). Interestingly, Pax9 expression is unaffected in Eya1/Six1 double mutants (Zou *et al.*, 2006). However, it remains

possible that Eya1 and Six1 may be regulated by Hoxa3 independently of Pax1 and 9 function.

The data just reviewed indicate the power of compound-mutant analysis for unraveling genetic interactions. However, further work is required to elucidate exactly how these and other transcription regulators cooperate in the development of the 3PP endoderm and to determine the precise role of each of these factors at the cellular level.

### Specification of the Thymus and Parathyroid

Prior to the overt formation of the thymus and parathyroid, the 3PP is specified into organ-specific domains. At E9.5, epithelial cells within the anterior dorsal aspect initiate expression of Gcm2, a transcription factor required for the development of the parathyroid (Gordon *et al.*, 2001). Current evidence suggests that Gcm2 acts downstream of Eya1 and Hoxa3, because Gcm2 is down-regulated in Hoxa3<sup>-/-</sup>, Eya1<sup>-/-</sup> and Hoxa3<sup>+/-</sup>;Pax1<sup>-/-</sup> compound mutant mice (Su *et al.*, 2001; Xu *et al.*, 2002; Blackburn and Manley, 2004). The first thymus specific transcription factor, Foxn1, is expressed at functionally relevant levels in the ventral domain of the 3PP from approximately E11.25, although low levels can be detected by PCR from E10.5 (Gordon *et al.*, 2001; Balciunaite *et al.*, 2002). Foxn1, a forkhead class transcription factor, is required for TEC differentiation and hair development, and is discussed in more detail in the next section. Upstream regulation of Foxn1 is currently not understood, and analysis of mutants in potential upstream regulators have not been informative in this regard. Hoxa3<sup>-/-</sup> and Eya1<sup>-/-</sup> embryos do not express Foxn1, but this is due to the block in primordium formation prior to the onset of Foxn1 expression. Although Foxn1 expression is unaltered in Pax9<sup>-/-</sup> and Hoxa3<sup>+/-</sup>;Pax1<sup>-/-</sup> mutants (Hetzer-Egger *et al.*, 2002; Su and Manley, 2000), the possibility remains of redundancy between Pax1 and Pax9. Although Six1<sup>-/-</sup> mutants display reduced Foxn1 expression, the 3PP exhibits increased cell death in the absence of Six1 (Zou *et al.*, 2006), and therefore the reduced expression of Foxn1 may reflect poor survival of Foxn1<sup>+</sup> cells rather than a direct interaction between Foxn1 and Six1. Further studies are required to determine whether a regulatory relationship exists between these genes and Foxn1.

The expression patterns of Foxn1 and Gcm2 clearly define the thymus and parathyroid domains of the 3PP. However, these factors do not appear to be responsible for specification of their respective organs, indicating that specification must be mediated by an upstream factor or factors. With respect to Foxn1, this model is supported by the finding that epithelial cells in the ventral domain of the 3PP express the thymus specific cytokine IL-7, a factor required for thymocyte differentiation throughout development, at E11.5 (von Freeden-Jeffry *et al.*, 1995; Zamisch *et al.*, 2005), making IL-7 one of the earliest currently identified markers of thymus identity. In the thymus primordium, IL-7 is regulated independently of Foxn1, because Foxn1<sup>-/-</sup>

embryos show normal IL-7 expression (Zamisch *et al.*, 2005), indicating that thymus identity is specified in the absence of Foxn1. Transplantation experiments also support this model, because E9.0 pharyngeal endoderm, which has not yet formed the 3PP, gives rise to a functional thymus when grafted ectopically (Gordon *et al.*, 2004), indicating that at this developmental stage some cells are already specified to the thymic epithelial lineage. Although Rhox4 has previously been identified as an early marker of thymus identity in the 3PP, the human orthologues of this gene are not expressed in human thymus organogenesis, making it unlikely that it plays a critical role in lineage specification (Morris *et al.*, 2006).

Similarly, our recent studies conclude that Gcm2 is not required for specification of the parathyroid, for other parathyroid-specific markers, including CCL21 and CaSR, are initiated but not maintained in Gcm2<sup>-/-</sup> mice (Z. Liu, S. Yu, and N. R. M., unpublished). Thus, Gcm2 may play an analogous role in parathyroid development to that of Foxn1 in the thymus.

How, then, are the thymus and parathyroid domains within the 3PP established? Evidence suggests that opposing gradients of bone morphogenetic proteins (BMP) and sonic hedgehog (Shh) may play an important role in this process. During thymus development, BMP4 expression is first detected at E9.5, when it is expressed by a small number of mesenchymal cells in the third pharyngeal arch (Patel *et al.*, 2006). By E10.5, the BMP4 expression domain has expanded to include the ventral 3PP endoderm and the adjacent mesenchyme but remains absent from the dorsal 3PP. This expression pattern is maintained at E11.5, and by E12.5 BMP4 is expressed throughout the thymic primordium and the surrounding mesenchymal capsule (Patel *et al.*, 2006). The expression pattern of BMP4 suggests that it may be responsible for the initiation of Foxn1 expression, because BMP4 is restricted to the ventral domain of the 3PP immediately prior to the onset of Foxn1 expression. Furthermore, Noggin expression is restricted to the dorsal anterior region of the 3PP at E10.5 and E11.5 and there is some *in vitro* evidence that BMP4 can directly regulate Foxn1 expression (Tsai *et al.*, 2003; A. Farley and C. C. B., unpublished data).

*In vivo* evidence of a role for BMPs in thymus organogenesis has been provided by a transgenic approach in which the BMP inhibitor Noggin is driven by the Foxn1 promoter, thus impairing BMP signaling in the thymic stroma (Bleul and Boehm, 2005). These mice have hypoplastic and cystic thymi that fail to migrate to their normal position above the heart. It is highly likely that this is due to a direct effect on the thymic stroma, because impaired development is evident prior to the immigration of lymphocytes, which are able to differentiate into T-cells. Furthermore, mediators of BMP signaling, such as Msx1 and phosphorylated Smad proteins, are down-regulated in both the epithelium and surrounding mesenchyme, suggesting that impaired

communication between these cell types is the mechanism responsible for the phenotype observed. Interestingly, Foxn1 expression was not overtly affected in this transgenic model, arguing against a role for BMP in the regulation of this transcription factor. However, the inhibition of BMP signaling is driven by the Foxn1 promoter, and thus it may occur after the point at which it is required for initiation of Foxn1 expression. In addition, since BMP2 and BMP7 are also expressed in the 3PP and common primordium (C. C. B. and N. R. M., unpublished data), it is highly likely that redundancy operates between different BMP family members. It may thus be more pertinent to view BMPs in terms of the signaling they mediate during organogenesis rather than which specific member of the BMP family is involved.

During development of the 3PP, expression of the secreted glycoprotein Shh is restricted to cells of the pouch opening at E10.5 and E11.5, although its receptor, Patched1, is expressed by cells in close proximity to this region (Moore-Scott and Manley, 2005). Analysis of Shh<sup>-/-</sup> embryos revealed that both the BMP4 and Foxn1 expression domains are expanded in the 3PP, while the corresponding Gcm2<sup>+</sup> parathyroid domain is lost in these mutants (Moore-Scott and Manley, 2005). Thus, the role of Shh in thymus organogenesis may be to oppose the action of BMP4 to allow the specification and development of the parathyroid.

Wnt glycoproteins may also be important in regulating Foxn1 expression. Wnts are expressed by the thymic stroma and lymphoid cells, although Wnt receptors are expressed exclusively by TECs (Balciunaite *et al.*, 2002). The earliest reported expression of Wnt family members during thymus development is at E10.5, immediately prior to strong Foxn1 expression, when the epithelium of the 3PP and adjacent cells express Wnt4 (Balciunaite *et al.*, 2002). Given this expression pattern and the finding that TEC lines that overexpress Wnt4 display elevated levels of Foxn1 (Balciunaite *et al.*, 2002), it is possible that Wnt4 cooperates with BMP4 to regulate Foxn1. Wnt 1, Wnt 4, and Wnt1, 4-null mice all exhibit hypoplastic thymi characterized by reduced T-cell numbers but normal thymocyte developmental progression. However, because no histological analysis of the thymi in these mutants has been presented, it is not possible to evaluate whether the primary effect is on the thymic epithelium or on thymocytes (Mulroy *et al.*, 2002; Staal and Clevers, 2005). As with BMP family members, functional redundancy is again a possibility, because other Wnt family members are also expressed in the 3PP and surrounding mesenchyme (Mulroy *et al.*, 2002; Balciunaite *et al.*, 2002; C. C. B. and N. R. M., unpublished data).

### Foxn1 and the Regulation of TEC Differentiation

As discussed earlier, the development of functionally mature TECs from the 3PP endoderm is cell autonomously dependent on Foxn1 (Blackburn *et al.*, 1996). Adult *nude* mice, which lack functional Foxn1, retain a cystic, alymphoid thymus consisting predominantly of apparently

immature epithelial cells (Cordier, 1974; Cordier and Haumont, 1980; Gordon *et al.*, 2001). These and other data (see earlier) suggest that lack of Foxn1 results in developmental arrest of thymic-epithelial-lineage cells at the founder/progenitor-cell stage of development. Thus, whereas TEPCs form independent of Foxn1, their differentiation into mature TEC subtypes depends on it. In the thymus, Foxn1 is expressed by all thymic epithelial cells throughout development and is maintained postnatally (Nehls *et al.*, 1996). It is also expressed in the hair follicles and epidermis, where it is required for normal development of the skin (Flanagan, 1966).

The precise role of Foxn1 has not been completely elucidated in either the thymic or the cutaneous epithelial lineages. However, considerable evidence suggests that it regulates the balance between epithelial proliferation and differentiation. Keratinocytes derived from Foxn1<sup>-/-</sup> mice have reduced proliferative capacity *in vitro* and prematurely express markers associated with terminal differentiation (Brissette *et al.*, 1996). Furthermore, when Foxn1 is over-expressed, markers associated with earlier stages of differentiation are up-regulated and later markers are absent (Brissette *et al.*, 1996). More recently it was shown that primary human keratinocytes can be induced to initiate terminal differentiation by transient expression of Foxn1 but that completion of the differentiation program is dependent on the levels of activated Akt, which may in turn be regulated by Foxn1 (Janes *et al.*, 2004). Thus, in the epidermis Foxn1 may function to ensure that terminal differentiation proceeds in a temporally regulated manner. Whether this is the case in the thymus is unclear. The early thymic rudiment in *nude* mice also shows reduced proliferation (Itoi *et al.*, 2001). However, the epithelial cells resemble immature progenitors and do not express markers of terminal differentiation.

There is some evidence to suggest that in the thymus, Foxn1 is required for lymphoepithelial cross-talk. Comparative gene expression analysis between *nude* and wild-type thymus suggests that PD1 Ligand is a target of Foxn1, because it is down-regulated in *nude* embryos (Bleul and Boehm, 2001). The receptor for PD1 ligand is expressed by thymocytes and has been implicated in thymocyte survival, proliferation and positive selection (Nishimura *et al.*, 1996, 2000), lending weight to the hypothesis that Foxn1 may regulate genes required for lymphoepithelial cross-talk.

A separate publication suggested a role for Foxn1 in cross-talk by analyzing Foxn1<sup>Δ/Δ</sup> mice, which express a splice variant lacking exon 3 of the N-terminal domain (Su *et al.*, 2003). Skin and hair development is normal in these mice, but the differentiation of TECs is suspended at a time equivalent to E13.5. Unlike the *nude* thymus, the thymic stroma can attract lymphocytes and mediate T-cell differentiation, although there are postnatal abnormalities in thymocyte maturation and a severe reduction in thymocyte numbers. The thymus-specific defect in Foxn1<sup>Δ/Δ</sup> mice resembles to

some degree the phenotype seen in hCD3ε26 mice, which have secondary blocks in TEC maturation due to suspended thymocyte development (Klug *et al.*, 1998, 2002). Based on this, we suggested that the N-terminal domain is required for lymphoepithelial cross-talk and as such has a thymus-specific function. However, the impairment of TEC differentiation in Foxn1<sup>Δ/Δ</sup> mice is more profound than in hCD3ε26 mutants and occurs prior to the stage when TEC development is dependant on lymphoepithelial cross-talk. It is therefore unclear if Foxn1 directly regulates genes involved in cross-talk or if its primary role is to regulate TEC differentiation, which has downstream effects on lymphoepithelial communication.

### Molecular Regulation of TEC Proliferation

Following the formation of the thymic primordium and the commitment of the epithelial cells to the TEC lineage, the thymus undergoes a period of expansion involving both the proliferation of stromal cells and an increase in thymocyte numbers. With regard to TECs, the growth factors Fgf7 and Fgf10 have been shown to be involved. *In vitro* experiments have demonstrated that both Fgf7 and Fgf10, which are expressed by the perithymic mesenchyme, can stimulate the proliferation of fetal TECs (Sunjara *et al.*, 2000). Furthermore, mice lacking Fgfr2IIb, the receptor for Fgf7 and Fgf10, have severely hypoplastic thymi, although they can support T-cell maturation, and Fgf10<sup>-/-</sup> mutants also develop hypoplastic thymi (Revest *et al.*, 2001).

### Noncanonical NF-κB Signaling Regulates mTEC Development

The development of mTECs depends on activation of the NF-κB signaling pathway, specifically the noncanonical pathway that culminates in RelB activation. Medullary TEC development is severely compromised in RelB-deficient mice (Burkly *et al.*, 1995; Weih *et al.*, 1995). In the noncanonical RelB activation pathway, ligand engagement of receptors in the TNFR family, such as lymphotoxinβ receptor (LTβR), activates NF-κB-inducing kinase (NIK), which phosphorylates homodimers of the downstream kinase, Ikkα. Activated Ikkα in turn phosphorylates the C-terminal region of NF-κB2 (p100), leading to ubiquitin-dependent degradation and release of the N-terminal polypeptide, p52. The formation of RelB/p52 heterodimers permits shuttling of RelB from the cytoplasm into the nucleus, where it functions as a transcriptional regulator (Bonizzi *et al.*, 2004). A range of medullary defects occurs in mice that are deficient in various components upstream of RelB in the alternative NF-κB activation pathway. Targeted disruption of the LTβR gene results in disorganized medullary regions that contain reduced numbers of both major mTECs subsets (Boehm *et al.*, 2003). Mice with a naturally occurring mutation in NIK (Barcena *et al.*, 1994) and Ikkα knockout mice have severe defects in medullary formation, including impairment of mTECs development and reduced expression of AIRE and

tissue-restricted antigens (Kajiura *et al.*, 2004; Kinoshita *et al.*, 2006; E. Richie, unpublished observations). A similar medullary phenotype is found in TRAF6 knockout mice (Akiyama *et al.*, 2005). Interestingly, each of these mutant strains develops autoimmune manifestations, indicating a breakdown in the establishment of central tolerance.

#### Role of Medullary Thymic Epithelial Cells in Establishing Central Tolerance

Medullary TECs have the unique ability to express genes encoding a wide array of antigens that initially were thought to be expressed only in peripheral tissues (Derbinski *et al.*, 2001). AIRE is expressed by mTECs and plays a prominent role in regulating tissue-restricted antigen expression. In humans, homozygous AIRE mutations result in a severe, multiorgan autoimmune disease termed *autoimmune polyglandular syndrome type 1* (Villasenor *et al.*, 2005). AIRE knockout mice develop a similar autoimmune phenotype due to defective clonal deletion, resulting in persistence of self-reactive thymocytes (Anderson *et al.*, 2002; Liston *et al.*, 2003). Although AIRE is clearly important for regulation of tissue-restricted antigen expression in mTECs, other as-yet-undefined factors are involved since certain tissue-restricted antigens are expressed even in the absence of AIRE (Derbinski *et al.*, 2005). Medullary TECs also affect central tolerance by supplying self-peptides to medullary dendritic cells (DCs) in a process termed *cross-presentation* (Gallegos and Bevan, 2004). Medullary TECs are also required for the generation of CD4<sup>+</sup>CD25<sup>+</sup> T regulatory (Treg) cells and natural killer T-cells, both of which actively repress self-reactive T-cells (Kronenberg and Rudensky, 2005; Kim *et al.*, 2006). Given that AIRE and tissue-restricted antigens are highly expressed by mTECs, it is likely that the autoimmune phenotype in mice deficient in various components of the

RelB activation pathway is a result of failed mTEC development. Taken together it is now clear that mTECs contribute directly and indirectly to establishing central tolerance and averting the development of autoimmunity.

## V. SUMMARY

Thymus organogenesis is a complex process in which a three-dimensional organ forms from the endoderm of the 3PP. The thymic epithelium, a critical regulator of thymopoiesis, comprises many subtypes of TEC, all of which arise from a common progenitor. Recent studies have begun to clarify the lineage relationships between these cell types and to identify the molecular factors that govern thymus organogenesis. However, several significant questions remain unresolved:

- What mechanisms regulate formation of the 3PP from the endoderm?
- How does the network of transcription factors and signaling molecules that are expressed in the endoderm and surrounding mesenchyme/mesoderm control subsequent 3PP development?
- What factor or factors specify thymus and parathyroid lineages within the 3PP?
- What are the factors responsible for the maintenance, proliferation and differentiation of TEPCs?

Additionally, important questions remain regarding homeostatic maintenance of the mature thymus, including elucidation of whether the postnatal organ is maintained by a stem cell mechanism, and the cellular and molecular mechanisms that operate to induce thymic involution. Resolution of these issues will permit the design of rational strategies for therapeutic reconstitution of the adaptive immune system. The development of such strategies should significantly impact the health of the aging population and other immunocompromised individuals.

## VI. ACKNOWLEDGMENTS

We wish to thank Lucy Morris (Carnegie Institution of Washington, D.C., and Howard Hughes Medical Institute, Baltimore), for critical reading of the manuscript, and our

funding bodies, Leukaemia Research (CCB, CSN), the EU (CCB, CSN), and the NIH (NRM, ER), for support.

### I. INTRODUCTION

This chapter defines the avenues via which stem cells contribute to the maintenance of the gastrointestinal tract in the normal state and in inflammatory disease. Much progress has recently been made to characterize and identify the intestinal epithelial stem cell. We have a strong interest in the intestinal stem cell niche, the key mediator of intestinal stem cell behavior. The stem cell niche is believed to be composed of the underlying mesenchymal cells, including the intestinal subepithelial myofibroblasts. The origins of the niche cells are not clear, although we have shown that a large proportion of intestinal myofibroblasts are derived from bone marrow cells and, moreover, that the contribution of bone marrow to intestinal myofibroblasts is significantly up-regulated in the inflamed colon. We have

shown that bone marrow cells also contribute to postnatal neovasculogenesis in the inflamed colon. We believe that this property of bone marrow stem cells, to redirect their lineage differentiation pathways and form mesenchymal and vascular lineages in response to specific regenerative signals, provides more clout than current evidence that bone marrow cells form epithelial cells in the gut as this is often not replicated, generally occurs to a very low degree, and the cellular mechanisms remain unclear with evidence that these cells may be a product of cell fusion rather than true differentiation. Indeed, bone marrow cells give rise to a far larger proportion of both myofibroblasts and vascular lineages in the gut, with a significant increase when placed under regenerative stress in the form of inflammatory disease. The role of bone marrow in tissue regeneration in

mouse models of colitis will be considered, with increasing evidence that bone marrow transplantation can alleviate Crohn's disease in humans, highlighting a possible role of bone marrow cells in the treatment of inflammatory disease, and defining a possible mechanism by which these cells provide this disease alleviation.

## II. DEFINING PROPERTIES OF ADULT STEM CELLS

Stem cells are located in most adult tissues and display several collective criteria, allowing identification and classification of these otherwise-indefinable cells. It is generally accepted that adult stem cells are located within a *niche*, formed and maintained by the subjacent mesenchymal cells and their secreted basement membrane factors, which serve to provide a specific milieu conducive to stem cell longevity, which is epitomized by the capacity of these cells for prolonged self-renewal. Stem cells are also capable of multilineage differentiation and form a specific repertoire of adult lineages within their native tissue, which is initiated by asymmetrical stem cell division to produce a transit amplifying (TA) cell, which becomes committed to differentiation and the formation of a specific, functional adult lineage. This latter characteristic has been somewhat revised in recent years, because we now know that stem cells within some tissues are not merely restricted to the formation of differentiated cells within their resident tissue, but can also form functional differentiated cell populations in tissues outside their own. This property, known as *stem cell plasticity*, has been confirmed in various disease and injury states in both humans and rodents, and we postulate that stem cells from one tissue can act as a *supplementary* stem cell population in response to specific stimuli released from a damaged or diseased tissue, possibly when regenerative pressure exceeds the capacity of the indigenous tissue stem cells. Stem cells appear to respond to these stimuli by homing to and engrafting within a damaged tissue, wherein they contribute to regeneration by differentiating to form a specific cell type. Stem cells in the bone marrow (BM) have frequently been shown to act in such a manner, i.e., as an auxiliary regenerative portion. This is fortuitous because BM provides a readily available source of well-characterized stem cells and has raised the potential of these cells as vectors for the delivery of therapeutic genes to a diseased tissue, although the extent of stem cell migration and differentiation between other tissues and the stimulatory signals and molecular mechanisms that initiate and regulate stem cell differentiation are unknown. Currently, the phenomenon of stem cell plasticity is not without stigma, for demonstrations of stem cell engraftment within a tissue often fail to be replicated, and the mechanism of stem cell differentiation is unclear, with evidence that in some tissues the cells merely fuse with an existing adult cell to form a heterokaryon.

In this chapter we discuss the role of the stem cells in the intestine in normal and inflamed states. We consider the recent growing evidence that BM transplantation appears to alleviate Crohn's disease, and we suggest a mechanism of action of the transplanted cells, i.e., via the formation of supporting regenerative cells in both the lamina propria and the blood vessels, which are important in tissue regeneration in inflammatory disease.

## III. CELLS OF THE INTESTINE

### Epithelial Cells

The epithelial lining of the intestine is folded into depressions known as *crypts*, which vary in size, depending on their location, and function to increase surface area to aid the absorption and digestion of nutrients from food. In the small intestine, in addition to the crypts, the surface area is further increased by the formation of luminal prominences known as *villi*. The fully differentiated cells of the crypts and villi are situated toward the luminal surface and are continually being shed into the lumen and replaced by a stream of proliferating progenitor cells. The columnar cells, termed *enterocytes* in the small intestine and *colono-cytes* in the colon, are the most abundant epithelial cell type in the mucosa, responsible for secretion and absorption. Columnar cells are polarized cells with a basal nucleus and an apical brush border composed of microvilli, which increase the surface area further. The *goblet* cells, so-called because of their characteristic shape, are dispersed throughout the small intestinal and colonic epithelium and secrete mucus into the intestinal lumen to lubricate the mucosa and to trap and expel microorganisms. The gastrointestinal tract is the largest endocrine organ in the body; hence the *endocrine*, *neuroendocrine*, or *enteroendocrine* cells are abundant throughout the epithelium, although in the small intestine they are more common to the crypts than the villi. The *Paneth* cells are almost exclusive to the crypt base of the small intestine and ascending colon. These cells maintain a sterile environment in the crypt via phagocytosis and the secretion of various antibacterial substances.

### Lamina Propria

The lamina propria is a layer of loose connective tissue that lies immediately subjacent to the epithelial mucosa throughout the gastrointestinal tract. The lamina propria is composed of mesenchymal cells and their secreted basement membrane factors; it is highly vascular, with lymphatic capillaries and nervous tissue (reviewed in Powell *et al.*, 1999). The lamina propria contains two myofibroblast subpopulations: the interstitial cells of Cajal (ICC) and the intestinal subepithelial myofibroblasts (ISEMFs).

### Intestinal Subepithelial Myofibroblasts

ISEMFs display cytologic characteristics of both fibroblasts and smooth muscle cells and are immunoreactive for

$\alpha$ -smooth muscle actin (SMA), vimentin, and smooth muscle myosin antigens, though they do not express desmin under normal circumstances (reviewed in Powell *et al.*, 1999). This antigenic phenotype permits their distinction from the vimentin-negative fibroblasts and the strongly desmin-positive smooth muscle cells. ISEMFs exist as a cellular syncytium in the subepithelial lamina propria and are most prominently expressed around the lower two-thirds of the crypts. ISEMFs proliferate and migrate upward along the crypt-villus axis until they reach the tip of the crypt or villi, where they are then shed into the intestinal lumen. The pattern and time frame of this myofibroblast migration is similar to that of murine epithelial cells (Wright and Alison, 1984). ISEMFs are adjoined to epithelial cells via gap and adherens junctions, which permit epithelial:mesenchymal interaction, and these cells have a broad range of functions, including the regulation of epithelial cell homeostasis, mucosal protection and wound healing, contraction and motility of small intestinal villi, and water and electrolyte transport in the colon (reviewed in Powell *et al.*, 1999).

### Intestinal Epithelial Stem Cells

The epithelial cells of the intestine are a continuously and rapidly renewing population. For example, the lining of the gastrointestinal tract is replaced every two to three days in rodents and other mammals (Wright and Alison, 1984). To regulate homeostasis, a vital balance between cell apoptosis, senescence, and the proliferation and differentiation of new cells must be maintained. This role is attributed to the intestinal stem cell, although, despite its significance as the most important regulatory element of intestinal function, limited evidence exists to definitively substantiate the location, quantity, regulatory pathways, or function of this elusive cell.

### Location of the Intestinal Epithelial Stem Cell

Since the polarized orientation of the differentiated cells in the intestinal crypts and villi is well characterized, it is presumed that a pool of progenitor cells exists at the origin of cellular migration that is responsible for this continuous cellular flux. The epithelial cells of the small intestine originate in the lower regions of the crypt and undergo proliferation and differentiation as they travel upward to be shed into the intestinal lumen, with the exception of the Paneth cells, which migrate downward to the crypt base. It is therefore generally accepted that the epithelial stem cell compartment is in the crypt base of the colon and at approximately cell position 4–5 in the small intestinal crypts, just superior to the Paneth cells (Potten *et al.*, 1997).

### Intestinal Stem Cell Niche

As with stem cells of most adult tissues, it is thought that the intestinal epithelial stem cells are located and maintained within a mesenchymal niche, situated near the base of the intestinal crypts. However, because intestinal stem

cells remain unidentified, it is not possible to localize the niche that underlies them; thus, our knowledge of the intestinal niche is based on circumstantial evidence and speculation. It is generally believed that epithelial stem cells are regulated by nonepithelial components, i.e., the mesenchymal cells and associated secreted factors in the lamina propria, which fits with the classical view of the composition of the stem cell niche (Spradling *et al.*, 2001) and is further supported by evidence of interactions between the ISEMFs and epithelial cells of the mucosa. For example, ISEMFs play vital roles in epithelial cell restitution, remodeling, fibrosis, and immunological and inflammatory responses via the secretion of specific growth factors and inflammatory cytokines (reviewed in Powell *et al.*, 1999). This epithelial:mesenchymal interaction highlights the ISEMF as a candidate component of the intestinal epithelial stem cell niche, although it is not clear if mesenchymal signals act directly on the stem cells or on the transiently differentiated daughter cells.

### Intestinal Stem Cell Number/Clonal Origins of Intestinal Crypts

#### Mouse

The number of stem cells within the gastrointestinal niche is a subject of ongoing debate. Investigations into the clonal origins of intestinal crypts have attempted to deduce whether they are monoclonal populations derived from a single stem cell or whether multiple stem cells proliferate to produce polyclonal crypts. The *Unitarian hypothesis* states that a single intestinal stem cell can clonally expand to produce the entire adult cell repertoire in the intestinal crypts (Cheng and Leblond, 1974). This is supported by evidence that a single surviving stem cell can recreate entire monoclonal crypts following irradiation damage (Ponder *et al.*, 1985), although these studies of damaged epithelium do not confirm that intestinal crypts are monoclonal under normal circumstances.

Mouse aggregation chimeras, wherein one parental strain bears a specific marker for the tissue of interest, have been used to investigate the Unitarian hypothesis. The binding capacity of the *Dolichos biflorus* agglutinin (DBA) lectin to the cells of the intestinal epithelium can be abolished by spontaneous mutation of the *Dlb-1* locus on chromosome 1 or by treatment with the chemical mutagen ethylnitrosourea (ENU). The SWR mouse has a carbohydrate polymorphism of *Dlb-1*; consequently, DBA binds to sites on the C57Bl/6J-derived, but not SWR-derived, cells in heterozygous C57Bl/6J(B6) $\leftrightarrow$ SWR mouse embryo aggregation chimeras. Intestinal crypts in neonatal B6 $\leftrightarrow$ SWR mice were polyclonal for the first two weeks after birth, suggesting that multiple stem cells exist during development (Schmidt *et al.*, 1988). However, all crypts eventually become monoclonal, possibly due to the positive selection of a single dominant clone or by the segregation of lineages due to the

division of crypts by *crypt fission*, which occurs frequently during this developmental period (Bjerknes and Cheng, 1999; Park *et al.*, 1995). The epithelial cells in the crypts remain monoclonal in the adult mouse intestine, confirming the existence of a single, sustainable stem cell (Bjerknes and Cheng, 1999; Ponder *et al.*, 1985; Winton and Ponder, 1990). Similarly, ENU treatment in B6 $\leftrightarrow$ SWR mice results in loss of DBA binding in mutated cells and revealed that small intestinal crypts are initially partially and then entirely negative for DBA staining (Winton *et al.*, 1988). It is proposed that ENU causes mutation of the *Dlb-1* locus in a stem cell, which then expands stochastically to produce a clone of cells that cannot bind DBA and remain unstained (Winton *et al.*, 1988). If this is the case, then a single stem cell can give rise to all the epithelial lineages within the small intestinal crypts.

In female mice with a heterozygous polymorphism of the X-linked gene glucose-6-phosphate dehydrogenase (*G6PD*), individual X chromosomes are distinguished by their natural “mosaic” pattern of *G6PD* immunohistological staining. Use of this model to investigate clonality in the intestinal crypts excludes the possibility that crypts derived from distinct strains in chimeric mice segregate differentially during organogenesis. The monophenotypic origin of murine intestinal crypts was confirmed following histochemical analyses in these mice, although the small intestinal villi showed a polyclonal derivation and are presumably formed by the upward migration of epithelial cells from multiple crypts (Thomas *et al.*, 1988). This is concordant with observations that crypts, although smaller than villi, are sevenfold more numerous in the mouse duodenum and fourfold more numerous in the ileum (Wright and Alison, 1984).

In both chimeric mice and the *G6PD* mouse model, the time taken for the decrease in partially mutated crypts and the emergence of entirely negative crypts to reach a plateau was approximately four weeks in the small intestine and 12 weeks in the large intestine, which was initially thought to be due to tissue differences in cell-cycle duration. However, an alternative explanation can be found in the *stem cell zone* hypothesis, which states that multiple stem cells occupy the crypt base at cell positions 1–4 and can undergo proliferation but do not differentiate until they have migrated to cell position 5. Paneth cells also appear initially at position 5, although these cells migrate downward to the crypt base (Bjerknes and Cheng, 1981). Based on this hypothesis, it was suggested that larger numbers of stem cells are present in the colon than in the small intestine, causing the difference in time taken for the mutant stem cells to expand stochastically and create monoclonal crypts (Williams *et al.*, 1992).

Alternatively, the temporal differences in the appearance of monophenotypic crypts in specific regions of the gastrointestinal tract may be due to differential rates of crypt fission at the time of mutagen administration (Park *et al.*, 1995). It was suggested that the stem cell number fluctuates throughout the crypt cycle until a threshold

number of cells is reached, thereby signaling crypt fission to occur (Loeffler *et al.*, 1997). Other reports state that between four and six stem cells located at cell position 4–5 from the base of the crypt, just superior to the Paneth cells, comprise the small intestinal stem cell population (Cai *et al.*, 1997; Potten *et al.*, 1997), and others claim that up to 16 or more stem cells can exist in a single intestinal crypt (Roberts *et al.*, 1995).

### Human

In humans, the intestinal crypts appear to be monoclonal and the small intestinal villi are polyclonal, analogous to the situation in the mouse. Perhaps the best evidence for the clonal origin of human intestinal crypts comes from a study of the colon of a rare XO/XY patient who had received a prophylactic colectomy for familial adenomatous polyposis (FAP). Nonisotopic *in situ* hybridization (NISH) using Y chromosome-specific probes showed that normal intestinal crypts were composed almost entirely of either Y chromosome-positive or Y chromosome-negative cells, with approximately 20% of crypts being XO. Immunostaining for neuroendocrine cell-specific markers was combined with NISH detection of the Y chromosome to show that these cells shared the same genotype as other crypt cells. The small intestinal villi epithelia were a mixture of XO and XY cells, in keeping with the notion that villi derive from stem cells of more than one crypt. Of the 12,614 crypts examined, only four crypts were composed of XO and XY cells, which was explained by nondisjunction with loss of the Y chromosome in a crypt stem cell (Novelli *et al.*, 1996). These observations agree with previous findings in chimeric mice that intestinal crypts are monoclonal and derive from a single multipotential stem cell.

Clonality studies are not strictly sustainable if they overlook the vital consideration of *patch size*, in which a *patch* is described as the number of cells of a single genotype within an area of tissue that is derived either from a single clone or from the coalescence of multiple clones of the same lineage (Schmidt *et al.*, 1985). Clonality must be determined at the patch edge, because it is not possible to decipher whether cells within the center of a patch are truly clonal or simply monophenotypic, formed from several stem cells of the same genotype. Heterozygosity for the *G6PD* Mediterranean mutation (563 C $\rightarrow$ T) is present in 17% of Sardinian females, permitting analyses of patch size by *G6PD* immunohistochemical staining. Of 10,538 colonic crypts analyzed from nine patients carrying the *G6PD* Mediterranean mutation, patch size in the colon was observed to be relatively large, containing up to 450 crypts. No evidence of any crypts with a mixed phenotype was observed in 2260 crypts located at the periphery of a patch, indicating that colonic crypts are indeed monoclonally derived (Novelli *et al.*, 2003). The Unitarian hypothesis, that all the differentiated epithelial lineages within the gastrointestinal tract share a common cell of origin, appears to apply to both mice and humans.

## IV. IDENTIFICATION OF INTESTINAL STEM CELLS

The maintenance of homeostasis of the intestinal epithelium involves an intricate and complex interplay of multiple regulatory mechanisms. It is therefore of great interest to uncover the molecular and cellular pathways that are required for normal intestinal function, starting, of course, with the ongoing quest to identify the intestinal epithelial stem cell and its niche.

### Crypt Fission and the Crypt Cycle

The intestinal crypts divide and replicate by a branching process known as *crypt fission*. In this process, the intestinal crypts undergo basal bifurcation and budding, leading to longitudinal division and the formation of identical daughter crypts. Elucidation of the process of crypt multiplication led to the notion that the intestinal crypts have a *crypt cycle* and finite life span, which was subsequently shown to be approximately two years in the mouse small intestine (Loeffler *et al.*, 1997). Because crypt fission begins at the bottom of the crypt, i.e., the location of the putative stem cells, it is possible that the stem cells initiate and regulate the formation of new crypts. Indeed, evidence is emerging that crypt fission may occur in the intestine when a maximal crypt size is reached (Park *et al.*, 1997).

A stochastic state-dependent model of stem cell growth proposes three possible outcomes when stem cells divide: *r*, in which a stem cell divides asymmetrically to produce one stem cell that is retained within the niche and one daughter cell that leaves the niche and becomes committed to differentiation; *p*, in which two stem cells are produced following symmetrical stem cell division; and *q*, in which stem cells divide symmetrically to produce two daughter cells that leave the niche and become transit amplifying cells (Loeffler *et al.*, 1993).

### DNA-Labeling Studies

A recent study of the mechanisms of stem cell division in the mouse small intestine has revealed that during asymmetrical division, stem cells retain an innate mechanism of genome protection. By labeling DNA template strands of the intestinal stem cells with tritiated thymidine ([<sup>3</sup>H]TdR) during development or in tissue regeneration and by bromodeoxyuridine (BrdUrd) labeling the newly synthesized daughter strands, both DNA strands can be visualized during cell division. Results showed that the original template DNA is retained within the stem cell and that the newly synthesized BrdUrd-labeled strands are passed on to the daughter cells, which leave the stem cell niche and become committed to differentiation. By discarding the newly transcribed DNA during asymmetrical cell division, the intestinal stem cell utilizes an inherent mechanism of genome protection, for this strand is more prone to replication-induced mutation (Potten *et al.*, 2002). This study supports the hypothesis of Cairns (1975), which suggests that selective retention of

the template DNA strand during stem cell division provides a means of protection against DNA replication errors.

### DNA Mutation Studies

An insight into stem cell organization in the crypts was gained from studies of the methylation pattern of nonexpressed genes in the colon. Phylogenetic analyses of random sequence variations in methylation tags of three neutral loci in cells of human colonic crypts can predict stem cell division histories and map cell fate. Cells in separate, unrelated crypts show variations in these methylation patterns, as expected, and cells closely opposed within one crypt display identical or closely related sequential methylation tags. This indicates that human colonic crypts contain multiple stem cells, which are constantly lost and replaced, eventually leading to a “bottleneck” effect, in which all cells are related to the closest stem cell ascendant and are monoclonally derived (Yatabe *et al.*, 2001).

Both inherited and spontaneous mutations occur frequently in the human mitochondrial genome. The high frequency of mitochondrial DNA (mtDNA) mutations and their accumulation within individual cells are a result of clonal expansion by genetic drift (Chinnery and Samuels, 1999) and can produce a defect in oxidative phosphorylation (Sciaccio *et al.*, 1994). Cells demonstrating >50% cytochrome-c oxidase enzyme function and normal succinate dehydrogenase (SDH) activity generally have increased numbers of mtDNA mutations (Johnson *et al.*, 1993). The biochemical function of samples of both normal and cancerous human colonic mucosa was deduced by sequencing their mtDNA and by histological analysis of cytochrome-c oxidase and SDH function. Cells with mutated mtDNA occupy part of the crypt and then clonally expand, resulting in entire colonization of a crypt by mutated cell, thus demonstrating the same process of *monoclonal conversion* as was observed in the *G6PD* mice, mentioned previously (Taylor *et al.*, 2003). Therefore, in humans, it appears that a single stem cell can form an entire crypt and then divide by crypt fission, demonstrated by the presence of stochastic mutations in mtDNA in both bifurcating arms of crypts undergoing fission (Taylor *et al.*, 2003). Moreover, mutations in crypts undergoing fission share the same genotype, which is different in cytochrome c-positive crypts; moreover, the genotype of neighboring mutated crypts is identical but differs from adjacent, nonmutated crypts. Patches of neighboring crypts deficient in cytochrome-c oxidase are clustered, and patches of mutated crypts increase in size with age, providing further evidence of the development of clonal patches in the human colon (Greaves *et al.*, 2006).

### Molecular Markers of Intestinal Stem Cells

#### Musashi and Hairy and Enhancer-of-Split Proteins

Musashi-1 (Msi-1) is highly expressed in mammalian neural stem cells (Sakakibara *et al.*, 1996). The transcrip-

tional repressor *Hairy* and *Enhancer-of-split* (*Hes*)-1 is essential for neural stem cell self-renewal and suppression of neural stem cell differentiation (Nakamura *et al.*, 2000). *Msi-1* positively regulates transcription of *Hes-1*, suggesting a close interaction between the two proteins, which is supported by their coexpression in cells just superior to the Paneth cells in the small intestine, the postulated stem cell zone. *Hes-1* expression in the mouse small intestine is more widespread than *Msi-1* expression, because *Hes-1* is also expressed, albeit in reduced levels, in epithelial cells migrating toward the villus tip. It is suggested that colocalization of *Msi-1* and *Hes-1* in cells just superior to the Paneth cells is indicative of the stem cell population in the mouse small intestine and that *Hes-1* expression alone represents proliferating cells committed to differentiation that have migrated outside the stem cell niche (Kayahara, 2003). *Musashi-1* mRNA and protein expression has also been confirmed in the putative stem cells in neonatal and adult intestinal crypts in mice (Potten *et al.*, 2003) and has recently been demonstrated in the human colon in epithelial cells located between positions 1 and 10 in the crypts (Nishimura *et al.*, 2003). These studies implicate *Musashi-1* as a possible gastrointestinal epithelial stem cell marker.

#### Repression of E-Cadherin

E-cadherin is a cell adhesion molecule with a well-established role in tumor suppression. E-cadherin is expressed in high levels in the intestinal epithelium and has been shown to regulate intestinal cell polarity and differentiation via the  $\beta$ -catenin/Tcf/LEF signaling pathway (Gottardi *et al.*, 2001), which is vital for normal intestinal epithelial cell function. A recent publication claims that differential E-cadherin expression in the epithelial cells along the human small intestine crypt–villus axis provides an insight into the nature of the hierarchical polar distribution of these cells and can be used to locate the intestinal epithelial stem cells. E-cadherin is absent from the cells in the base of the human small intestinal crypts, at approximately cell position 5–7. Forced expression of E-cadherin in those cells caused a decrease in proliferation and promoted cell junction formation, thereby inhibiting cell migration. It is therefore proposed that E-cadherin represents a marker of intestinal epithelial stem cells and plays an important role in regulating stem cell behavior. However, the inability of E-cadherin to induce terminal differentiation of enterocytes indicates that it acts in conjunction with other proteins (Escafit *et al.*, 2005).

## V. PATHWAYS OF CELLULAR DIFFERENTIATION IN THE INTESTINE

An increasing number of genes and their ligands and receptors are being identified that are expressed by epithelial and mesenchymal cells in the gastrointestinal tract and are involved in the regulatory molecular pathways of

epithelial cell function in both the normal and neoplastic gastrointestinal mucosa. The ongoing elucidation of these molecular pathways is key to providing an insight into the location and the behavior of the intestinal epithelial stem cell.

### Wnt/ $\beta$ -Catenin Signaling Pathway

The central player in the canonical Wnt signaling pathway is the cytoplasmic protein beta ( $\beta$ )-catenin, whose stability is regulated by the APC tumor suppressor complex. When Wnt receptors are not engaged, APC forms a subcellular, trimeric complex with axin and glycogen synthase kinase-3 $\beta$  (GSK3 $\beta$ ), which triggers the phosphorylation, ubiquitination, and proteosomal degradation of  $\beta$ -catenin. Wnt stimulation activates the cytoplasmic phosphoprotein “disheveled” through its receptor, “frizzled,” causing inhibition of GSK3 $\beta$  and a resultant accumulation of cytosolic  $\beta$ -catenin. Beta-catenin then translocates into the nucleus and interacts with members of the T-cell factor/lymphoid-enhancing factor (Tcf/LEF) family of DNA-binding proteins, transiently converting them from transcriptional repressors to activators, and signaling the activation of downstream target genes that increase cellular proliferation. When the Wnt signal is removed, APC extracts  $\beta$ -catenin from the nucleus, and the transcriptional repressor function of Tcf is restored (reviewed in Sancho *et al.*, 2004).

The Wnt/ $\beta$ -catenin pathway plays a role in malignant transformation. A mutation in APC renders the GSK3 $\beta$ /Axin/APC complex incapable of destabilizing  $\beta$ -catenin, leading to an accumulation of nuclear  $\beta$ -catenin/Tcf/LEF complexes and an increase in target gene transcription and cell proliferation, which can cause tumor formation (Wielenga *et al.*, 1999).

### Tcf/LEF DNA-Binding Protein Family

There are four known members of this family of transcription factors: Tcf-1, LEF1, Tcf-3, and Tcf-4. Tcf-4 is expressed in high levels in the developing intestine from embryonic day (E) 13.5 and in the epithelium of the adult small intestine and colon and in colon carcinomas (Barker *et al.*, 1999). In patients with a loss of function of the APC or  $\beta$ -catenin genes, nuclear accumulation of  $\beta$ -catenin/Tcf-4/LEF complexes in colonic epithelial cells implicates Tcf-4 in the ensuing uncontrolled target gene transcription and subsequent up-regulation of cell proliferation, which can often lead to tumorigenesis (Barker *et al.*, 1999). In the absence of  $\beta$ -catenin, the Tcf/LEF family recruits the corepressor proteins “Groucho” and CREB-binding protein (CBP) to the downstream Wnt target genes and inhibits their transcription (reviewed in Barker *et al.*, 2000). The Tcf-4 knockout mouse is devoid of proliferating cells in the small intestine and is presumed to lack a functional stem cell compartment. It is postulated that Tcf-4 is vital for the establishment of the intestinal stem cell population and is activated by a Wnt signal from the underlying stroma (Korinek *et al.*, 1998),

further evidence that mesenchymal cells in the lamina propria comprise the intestinal stem cell niche.

### Cdx-1 and Cdx-2 Homeobox Genes

The mammalian homeobox proteins Cdx-1 and Cdx-2 also play an important role in intestinal epithelial stem cell transcriptional regulation, with a particular influence on gastrointestinal metaplasia. Cdx-1 is expressed throughout the proliferative compartment of the developing and adult mouse intestinal crypt epithelium (Subramanian *et al.*, 1998), and both Cdx-1 and Cdx-2 mRNAs show restricted expression in the epithelial mucosa of the human small intestine and colon (Mizoshita *et al.*, 2001). The Tcf-4 knockout mouse, mentioned earlier, does not express Cdx-1 in the small intestinal epithelium, implying that Cdx-1 is a direct downstream target of the Tcf-4/ $\beta$ -catenin complex in the Wnt signaling pathway and is employed in the development of the epithelial stem cell niche (Lickert *et al.*, 2000). Expression of Cdx-1 is reduced in proliferating epithelial cell nuclei in colonic crypts concurrent with their progression to adenomas and adenocarcinomas (Lickert *et al.*, 2000), although, because no colonic tumors develop in the Cdx-1 null mouse, this molecule does not appear to have direct tumor-suppressing properties (Subramanian *et al.*, 1998). Cdx-2 is expressed in all epithelial cell nuclei in the upper regions of the crypts of the descending colon to the rectum, with decreasing expression parallel to an increasing degree of dysplasia in these cells (Ee *et al.*, 1995). Region-specific genes such as Cdx-1, Cdx-2, and Tcf-4 appear to define the morphological features of the specialized regions of the intestinal epithelium and regulate stem cell function.

### Forkhead Family of Transcription Factors

The forkhead, or winged helix, family of transcription factors, of which there are nine members identified in mice, produce the Fox (forkhead box) proteins (reviewed in Kaestner *et al.*, 2000). Mice with a heterozygous targeted mutation of the forkhead homolog 6 (*fkf-6*), or *Foxl* gene, which is ordinarily expressed by gastrointestinal mesenchymal cells, display an atypical gastrointestinal epithelium with branched and elongated glands in the stomach, elongated villi, hyperproliferative crypts, and goblet cell hyperplasia due to increased epithelial cell proliferation. These *Foxl* mutants have increased levels of heparin sulfate proteoglycans (HSPGs), causing overactivation of the Wnt/ $\beta$ -catenin pathway and an increase in target cell proliferation, demonstrating an indirect regulation of the Wnt/ $\beta$ -catenin pathway by *Foxl*-mediated HSPG production (Kaestner *et al.*, 1997).

### TGF- $\beta$ /Smad Signaling Pathway

The transforming growth factor TGF- $\beta$  family inhibits gastrointestinal epithelial cell proliferation and is predominantly expressed in the differentiated compartments of the gut (Winesett *et al.*, 1996). Under normal circumstances,

TGF- $\beta$  forms a multimeric complex with two serine-threonine kinase surface receptor molecules: TGF- $\beta$  type I (TGF $\beta$ RI) and type II (TGF $\beta$ RII). The intracellular messengers of the TGF- $\beta$  signaling pathways are the cytoplasmic Smad proteins, and Smad2 and Smad3 are phosphorylated upon activation of the TGF- $\beta$  receptors and form a heteromeric complex with Smad4. This complex then translocates to the nucleus, where it interacts with transcriptional coactivators and corepressors to regulate TGF- $\beta$  target gene transcription (Miyazono, 2000).

Disruption of TGF- $\beta$ /Smad signaling causes intestinal epithelial cell hyperproliferation, and Smad2, Smad4, and TGF $\beta$ RII are frequently inactivated in human cancers, confirming their function as tumor suppressor genes (Grady *et al.*, 1999). Lack of TGF- $\beta$  signaling in the intestine appears to contribute to the progression of early preexisting lesions (reviewed in Sancho *et al.*, 2004). For example, mice with targeted heterozygous mutations in the Smad4 and APC genes develop adenomatous polyps in the small intestine and colon due to loss of heterozygosity (LOH) of the APC and Smad4 wild-type alleles. This implies a reciprocal interaction between the TGF- $\beta$  and Wnt signaling pathways in the progression of intestinal carcinogenesis, in which LOH of genes from both pathways is required before malignant transformation can occur (Takaku *et al.*, 1998).

### Notch Signaling Pathway

Notch encodes a large, single transmembrane receptor, of which there are four mammalian isoforms (Notch 1–4) and five corresponding ligands (Delta-like 1, 3, and 4; Jagged 1 and 2) (reviewed in Sancho *et al.*, 2004). The Notch signaling pathway regulates gastrointestinal epithelial cell fate and the differentiation of the four specialized epithelial lineages of the gastrointestinal tract. This pathway supports the Unitarian hypothesis, that a single stem cell gives rise to all mature intestinal epithelial cell lineages (Cheng and Leblond, 1974). Increased levels of Notch protein negatively regulate transcription of *Math1*, via upregulation of the *Hes1* transcriptional repressor. Mice with a targeted deletion of *Math1* fail to develop goblet, Paneth, and enteroendocrine cell lineages in the small intestine, and these *Math1*-negative epithelial cell progenitors solely form enterocytes (Yang *et al.*, 2001). Conversely, a reduced Notch expression and subsequent accumulation of its ligand, Delta, increases *Math1* expression by blocking *Hes1*, causing cells to transdifferentiate to form goblet, Paneth, and enteroendocrine lineages in the small intestine (van Den Brink *et al.*, 2001). *Hes1* knockout mice display an elevated *Math1* expression, with a concurrent increase in the numbers of goblet, Paneth, and enteroendocrine cells and a reduced enterocyte population (Jensen *et al.*, 2000). These results suggest that the absorptive versus secretory cell fate decision is established through the Notch-*Hes1* pathways, although aberrant Notch signaling in intestinal tumorigenesis has not been described to date (reviewed in Sancho *et al.*, 2004).

## VI. ADULT STEM CELL PLASTICITY

An expanse of evidence regarding the surprisingly flexible potential of adult stem cells in their differentiation repertoires has recently challenged the classical belief that tissue stem cells are restricted to the production of adult lineages within their tissue of residence. Consequent to this discovery, stem cells now represent an entirely new field of regenerative medicine and may hold the key to the treatment of a number of diseases, such as cancer, cardiovascular disease, neurodegenerative disease, and diabetes. Recently, a vast number of reports have emerged showing that adult stem cells retain a large degree of plasticity and can differentiate to form many functional adult cells within extraneous tissues. Much of this research has focused on the adult BM as an easily accessible source of cells that have the potential to cross lineage boundaries, and transplanted adult BM cells have been shown to form adult cell types in many different tissues, including the liver, kidney, heart, CNS, gastrointestinal tract, lung, and skin (reviewed in Poulsom *et al.*, 2002).

It appears that selection pressure induced by target organ damage can intensify the efficacy of this process; e.g., increased numbers of cells of BM origin were observed in gastrointestinal epithelia of BM-transplanted humans with graft-versus-host disease (GvHD) or intestinal ulceration (Okamoto *et al.*, 2002). It is proposed that BM cells respond to specific signals from damaged or diseased tissues, whereupon they migrate to and engraft within this tissue and aid regeneration and remodeling by contributing to differentiated adult cells.

It is important to demonstrate that BM-derived adult cells are functional, with a capacity to restore diseased or damaged tissues, and thus convey a possible clinical relevance. The fumarylaceto-acetate hydrolase-deficient (Fah<sup>-/-</sup>) mouse model of the human metabolic liver disease, Type 1 tyrosinaemia, was used to confirm the functional significance of BM cell plasticity (Lagasse *et al.*, 2000). Fah<sup>-/-</sup> mice were transplanted with as few as 50 purified hematopoietic stem cells (HSCs), which traveled to the liver and restored enzyme levels to normal by forming Fah-expressing hepatocytes, thereby rescuing the mice from their fatal deficiency (Lagasse *et al.*, 2000).

## VII. BONE MARROW CONTRIBUTION TO THE CELLS IN THE ADULT INTESTINE

There is a growing number of reports that BM cells can repopulate both epithelial and mesenchymal lineages in the gastrointestinal tract of animals and man. A seminal paper by Krause and colleagues (2001) demonstrated the remarkable plasticity of a single purified BM cell, forming epithelial cells in the murine lung, skin, and gastrointestinal tract. A highly purified population of mesenchymal stem cells (MSCs), termed MAPCs, were isolated from ROSA26 mice and constitutively express  $\beta$ -galactosidase and were micro-injected into mouse blastocysts following 55–65 population

doublings, which were then transferred to foster mothers and allowed to develop and be born. Chimeric offspring were killed at 6–20 weeks, and BM-derived epithelial cells were observed in many somatic tissues, including the small intestine (Jiang, 2002).

A recent paper investigating long-term repopulation of murine intestinal epithelium by BM cells found that BM contributes to all intestinal lineages in both normal and neoplastic epithelium. However, donor-derived cells were present in only 0.05% of total crypts, and only a very small proportion of epithelial cells were BM derived. The authors report that of these cells, 51% were a product of cell fusion, presumably with an existing intestinal progenitor or stem cell (Rizvi *et al.*, 2006). However, it cannot be concluded that fusion is the sole means by which BM cells contribute to intestinal epithelial lineages in this model, for up to 40% of BM-derived cells remained unaccounted for, and other mechanisms, including true differentiation, cannot be discounted.

Perhaps the most striking demonstration of BM contribution to cells in the gastrointestinal tract was shown by Houghton and colleagues (2004), using a well-established model of gastric carcinoma. Donor BM from ROSA26 mice was transplanted into wild-type mice that were then infected with *Helicobacter felis*. Gastric mucosal apoptosis was present at six to eight weeks postinfection, donor-derived mucosal cells were observed in the gastric glands from 20 weeks posttransplant, and by 52 weeks up to 90% of the gastric mucosa was composed of BM-derived cells, which thus appear to home to and repopulate the gastric mucosa and contribute to metaplasia, dysplasia, and cancer. Three separate methods were utilized to investigate the fusion hypothesis, leading to the conclusion that stable fusion did not occur (Houghton *et al.*, 2004).

BM-derived epithelial cells have also been observed throughout the gastrointestinal tract in humans following sex-mismatched BM transplantation (Korbling *et al.*, 2002; Okamoto *et al.*, 2002; Spyridonidis *et al.*, 2004), and heterokaryon formation was ruled out as the mechanism by which BM cells form intestinal epithelial cells (Matsumoto *et al.*, 2005).

It is important to note that observed donor-derived epithelial cells in the mouse and human gastrointestinal tract are most frequently single cells randomly interspersed throughout the crypts and villi and that the incidence of these cells is low, ranging from 0.04% (Spyridonidis *et al.*, 2004) to approximately 10% (Jiang, 2002). However, the BM contribution to epithelial cells in human intestinal biopsies was increased between 5- and 50-fold in tissue damaged by GvHD, compared to intact epithelium (Okamoto *et al.*, 2002; Spyridonidis *et al.*, 2004). The low levels of engraftment and the lack of clusters of donor-derived cells indicate that it is unlikely that the BM cells form intestinal epithelial stem cells, supported recently by a lack of Musashi-1 expression by BM-derived intestinal epithelial cells in humans (Matsumoto *et al.*, 2005). However, a small proportion

of BM-derived gastrointestinal epithelial cells expressed the proliferative marker Ki-67 and a larger proportion of expressed markers of terminal differentiation (interestingly, transplanted cells contributed to all four lineages present in the gastrointestinal epithelia), which indicates that BM cells contribute to tissue turnover (Matsumoto *et al.*, 2005).

### VIII. ORIGIN OF THE ISEMFs

The origin of the ISEMFs is unresolved, with reports of transdifferentiation between different mesenchymal cell types, including resident tissue fibroblasts (Gabbiani, 1996) or smooth muscle cells (Rønnov-Jessen *et al.*, 1995), or a putative stem cell population in the lamina propria near the crypt base (Bockman and Sohal, 1998; Marsh and Trier,

1974a, 1974b). However, more recent data from *in vitro* studies indicate that cells in the BM can differentiate to produce myofibroblast-like cells (Ball *et al.*, 2004; Emura *et al.*, 2000). We have recently confirmed this finding *in vivo* in the intestines of both mice and humans. Following lethal irradiation and transplantation of whole BM cells in mice, almost 60% of ISEMFs were derived from the donor cells six weeks posttransplant. These cells are present as interconnected rows, indicative of clonal expansion, and appear to be located predominantly around the crypt base, strong evidence that they contribute to the putative intestinal epithelial stem cell niche (Fig. 45.1A–F; Brittan *et al.*, 2002). Since this initial finding, that BM cells contribute to a large proportion of myofibroblasts in the gut, transplanted BM cells

**FIG. 45.1.** BM-derived myofibroblasts in a model of chemically induced colitis. Female mice received a bone marrow transplant from male donor mice, and BM-derived myofibroblasts were identified by morphologic criteria, SMA immunoreactivity (red cytoplasm), and Y chromosome-expression (dark brown nuclear spot). These cells were frequently identified at all time points in both **(A)** ethanol-treated controls (four days after administration of ethanol, arrow) and **(B and C)** TNBS-treated mice (noninflamed mucosa adjacent to colitis eight days after administration of TNBS, arrows). BM-derived myofibroblasts were often present as cellular columns spanning from the epithelial crypt base to the intestinal lumen **(D)**: six days after administration of ethanol; **E and F** [inset]: six days after administration of TNBS, arrows). **(G)** Activated myofibroblasts in colitis were identified by their location in regions of fibrosis and by their large, flat shape (six days after administration of TNBS, arrows). **(H and I** [inset]) BM-derived activated myofibroblasts were present in the submucosa in regions of regenerating epithelium (eight days after administration of TNBS, arrows). n, necrotic epithelial crypts; u, mucosal ulcer; f, fibrosis; re, epithelialization.

**FIG. 45.2.** BM contributions can form entire blood vessels in TNBS-induced colitis. **(A and B)** BM-derived vascular smooth muscle lining cells were identified as smooth muscle–like cells surrounding the blood vessels that were SMA immunoreactive (red cytoplasm) and possessed the Y chromosome (dark brown nuclear spot). The role of BM in postnatal vasculogenesis was confirmed by the presence of whole blood vessels composed entirely of BM-derived cells (arrows).

have since been shown to contribute to large proportions of myofibroblasts and fibroblasts in several other organs, including the mouse lung, stomach, esophagus, skin, kidney, and adrenal glands (Direkze *et al.*, 2003) and the human liver in fibrosis (Forbes *et al.*, 2004), and BM can maintain differentiated cell production within a damaged tissue for extensive lengths of time; e.g., in one patient, approximately 23% of myofibroblasts in the fibrotic liver were BM derived two years posttransplant (Forbes *et al.*, 2004).

### ISEMFs in Tissue Regeneration in Inflammatory Bowel Disease

In the normal, healthy gut, ISEMFs are present as spindle-shaped, transiently differentiated cells. However, in inflamed tissue, ISEMFs become activated and assume a round, flattened morphology, with an accelerated proliferation rate (McKaig *et al.*, 2002), increased expression of cytokines, chemokines, growth factors, and adhesion molecules, and enhanced secretion of soluble mediators of inflammation and extracellular matrix factors (reviewed in Powell *et al.*, 1999a, 1999b). Furthermore, overactivation and persistence of activated ISEMFs causes tissue fibrosis and scarring in Crohn's disease (Aigner *et al.*, 1997; Isaji *et al.*, 1994; Kinzler and Vogelstein, 1998). We showed that BM-derived ISEMFs appear capable of activated response in the mouse, for the contribution of transplanted BM cells to ISEMFs is significantly up-regulated in a model of chemically induced inflammatory bowel disease, similar to Crohn's disease in humans, and that these BM-derived cells display an activated phenotype (Fig. 45.1G–I; Brittan *et al.*, 2005). In a separate study, the role of BM was investigated in a model of spontaneous colonic inflammation, the interleukin-10 knockout mouse (IL10<sup>-/-</sup>). Following whole BM transplantation from wild-type mice, inflammatory disease in the colons of IL10<sup>-/-</sup> mice was ameliorated, and approximately 30% of ISEMFs were of donor origin, whereas IL10<sup>-/-</sup> mice receiving IL10<sup>-/-</sup> BM progressed to extensive colitis, with up to 45% of myofibroblasts originating from the transplanted cells. Interestingly, wild-type mice that received bone

marrow from either IL10<sup>-/-</sup> mice or wild-type mice showed no progression to an inflammatory phenotype, despite replacement of the hematopoietic lineages by the transplanted cells (Bamba *et al.*, 2006). The implications of these findings, that the contribution of BM to ISEMFs is significantly up-regulated in the inflamed gut in response to regenerative pressure, is discussed later in relation to a possible therapy for Crohn's disease.

## IX. BONE MARROW-DERIVED VASCULAR LINEAGES CONTRIBUTE TO TISSUE REGENERATION IN IBD

The contribution of BM-derived EPCs to neovascularization in many inflammatory conditions is now well documented. In addition to the significant contribution of BM cells to ISEMFs in colitis, we also observed a large contribution of BM cells to multiple vascular lineages in these mice (Brittan *et al.*, 2005). In patches of severe inflammation, vessels were observed that appeared to be composed largely, and even entirely, of BM-derived cells, suggesting that BM is involved in the creation of entire new blood vessels via postnatal neovascogenesis (Fig. 45.2). Quantification of the proportion of BM-derived mural cell-containing vessels revealed a statistically significant 6.4-fold increase in colitis as compared to ethanol-treated controls ( $p = 0.013$ ); moreover, the total percentage of BM-derived mural cells within blood vessels was calculated, showing an almost twofold increase in the contribution of BM to mural cells in colitis, compared to ethanol-control tissue ( $p = 0.017$ ). BM cells also formed endothelial cells within blood vessels in inflamed colons, ascertained by their morphology and their coexpression of ICAM-1 and the Y chromosome (Brittan *et al.*, 2005).

Expression of the intracellular adhesion molecule ICAM-3 (CD50) is up-regulated in Crohn's disease (Bretscher *et al.*, 2000; Vainer and Nielsen, 2000), and ICAM-3 has recently been shown to be expressed on BM-derived endothelial cells and to play a regulatory role in endothelial cell junction formation (van Buul *et al.*, 2004), possibly support-

ing our evidence for neovasculogenesis by BM-derived endothelial cells in colitis.

There are numerous reports of BM-derived endothelial cells, although few studies describe BM-derived mural cells. A recent report describes a BM origin of the periendothelial vascular mural cells, which are believed to be mural cell progenitors (Rajantie *et al.*, 2004). It has not yet been possible to purify EPCs from the mouse BM, although it is suggested that they derive from a population of HSCs that express Flk-1, c-Kit, Sca-1, CD34, and CD45 but lack markers of lineage differentiation (Lin<sup>-</sup>) (Asahara and Kawamoto, 2004). MSC-derived MAPCs, mentioned previously, isolated from both murine and human BM have also been shown to have endothelial differentiation potential, both *in vivo* and *in vitro* (Jiang, 2002; Reyes *et al.*, 2002).

Paris and colleagues (2001) presented data showing that the initiating factor in radiation-induced crypt death in mice is apoptosis of the endothelial cells in the tissue stroma, which precedes intestinal epithelial stem cell dysfunction and crypt damage. The authors proposed that the endothelial cells are the primary targets of gamma radiation and that the concurrent death of the epithelial stem cells is a secondary event, caused by a loss of endothelial cell support. However, these claims have never been corroborated and were refuted due to the lack of tissue ischemia and hypoxia that would be expected following such severe damage to the vasculature (Hendry *et al.*, 2001). With respect to our current findings of BM-derived endothelial cells in the mouse colon, it is important to note that if the endothelial cells in the intestine are the primary targets of radiation-induced intestinal mucosal damage, then this implicates the BM with a further role in intestinal epithelial stem cell regulation, via the formation of endothelial cells.

## X. STEM CELL PLASTICITY: DE NOVO CELL GENERATION OR HETEROKARYON FORMATION

It is becoming increasingly apparent that two separate mechanisms of stem cell plasticity exist: *de novo* cell generation through BM cell differentiation, and fusion of BM cells with preexisting cells to form a cell with multiple, genetically variant nuclei, a heterokaryon. The classic gold standard proof-of-principle model for adult stem cell plasticity was demonstrated by the rescue of the Fah<sup>-/-</sup> mouse from its fatal metabolic disease by BM stem cell transplantation (Lagasse *et al.*, 2000), mentioned previously, which definitively showed that BM-derived hepatocytes were functionally normal. However, cytogenetic analyses showed that almost all the newly formed, Fah-synthesizing hepatocytes in these transplanted mice expressed a karyotype indicative that fusion had occurred between a transplanted BM cell and a host hepatocyte (Vassilopoulos *et al.*, 2003; Wang *et al.*, 2003). It is important to consider that hepatocytes are frequently polyploid and express multiple sets of chromo-

somes, and it is thereby possible that the liver presents a unique environment for the formation of fused hybrid cells (reviewed in Alison *et al.*, 2004).

Transplanted BM stem cells have been shown to fuse with Purkinje cells in brains of both mice (Weimann *et al.*, 2003b) and humans (Weimann *et al.*, 2003a). In the SOD1 mouse, which develops a lethal form of human ALS, BM cells can form adult cells in the CNS, heart, and skeletal muscle, thereby prolonging animals' survival (Corti *et al.*, 2004). Examination of nuclear content by FISH analyses suggested that BM-derived neurons may be a result of cell fusion, although in the brains of some male mice that had received a female BM transplant, neurons were seen that did not express a Y chromosome, which could be explained by *de novo* cell formation by transplanted female BM cells or, alternatively, may simply be a result of incomplete detection by the FISH technique (Corti *et al.*, 2004). Conversely, in the human brain, transplanted BM cells appear capable of neurogenesis and contribute to approximately 1% of all neurons for up to six years posttransplant. Analyses of autopsy brain specimens from three female patients that received a male BM transplant showed no evidence of fusion, for only one X chromosome was present in all male-derived neurons (Cogle *et al.*, 2004).

Whereas studies of sex chromosomal content may prove ambiguous due to artifacts created by the *in situ* hybridization technique, the Cre/lox recombinase system provides an elegant means of studying the mechanism of adult stem cell plasticity, using mice of the Z/EG Cre-reporter strain. The Z/EG transgenic mouse expresses a transgene cassette consisting of the chicken  $\beta$ -actin promoter driving expression of a  $\beta$ -galactosidase/neomycin-STOP reporter gene. This is flanked by two loxP sites and followed downstream by enhanced green fluorescent protein (eGFP) expression. Expression of  $\beta$ -galactosidase alone is driven by the  $\beta$ -actin promoter until Cre-mediated recombination occurs, at which point the  $\beta$ -galactosidase-STOP DNA is excised and the downstream eGFP is expressed instead. BM from male Z/EG mice was transplanted into female mice that ubiquitously expressed Cre, and cells within multiple tissues were analyzed for eGFP or  $\beta$ -galactosidase expression, i.e., any cell resulting from the fusion of a BM cell with a host cell should express eGFP, and any cell that expresses  $\beta$ -galactosidase is the product of BM cell differentiation. However, recent reports using the Cre/lox recombinase system have also proved inconsistent, because BM-derived epithelial cells in the mouse liver, lung, and skin were shown by this method to form without cell fusion (Harris *et al.*, 2004), whereas results of Alvarez-Dolado and colleagues (2003), using a similar system, clearly demonstrated that BM cells spontaneously fuse with hepatocytes in the liver, Purkinje cells in the CNS, and cardiomyocytes in the heart, with no evidence of *de novo* generation.

Evidence of heterokaryon formation following stem cell transplantation in the gastrointestinal tract or skin has not

been reported to date, and gastrointestinal epithelial cells derived from transplanted mobilized peripheral blood stem cells were reported to contain a normal ratio of sex chromosomes (Korbling *et al.*, 2002). An important observation was made, in that in some reported incidences of spontaneous cell fusion, the original stem cell markers are repressed and the transplanted cells appear to reprogram their new “host” nuclei to produce a sustainable, functional cell (Weimann *et al.*, 2003). Additionally, the incidence of heterokaryons was shown to increase as a tissue ages, suggesting that BM-derived cells can divide (Weimann *et al.*, 2003). The underlying principle, that transplanted BM cells have the capacity to rescue an otherwise-fatal metabolic disease, is maintained and should not be overlooked, although it is irrefutable that before we overlook, or indeed overstate, the capacity of adult stem cells to regenerate damaged or diseased tissue, further clarification of the mechanisms involved in this apparent stem cell plasticity is essential.

However, despite our lack of knowledge of the mechanisms involved, the desired endpoint of bone marrow transplantation as a cure for otherwise-lethal conditions has been demonstrated. Marcus Grompe and colleagues showed that hematopoietic bone marrow stem cell transplantation prevented lethality in the fumarylacetoacetate hydrolase (FAH)-deficient mouse, a model of fatal hereditary Type 1 tyrosinaemia (Lagasse *et al.*, 2000). Following karyotyping, this was shown to be due to the transplanted cells’ fusing with the indigenous hepatocytes, forming cells with an abnormal number of chromosomes, and somehow stimulating their production of the defunct enzyme (Wang *et al.*, 2003). The authors have since reported that newly formed heterokaryons may undergo *reduction division*, in which nuclear chromosome content is returned to normal.

Therefore, it is apparent that much progress must be made before a clinical application of adult stem cells should be considered, although at this stage it would surely be inju-

dicious to ignore the obvious potential of adult stem cells for tissue regeneration.

## XI. BONE MARROW TRANSPLANTATION AS A POTENTIAL THERAPY FOR CROHN’S DISEASE

As discussed previously, in mice with either chemically induced or spontaneous inflammatory bowel disease, the engraftment of transplanted bone marrow cells into the damaged gut and their formation of activated myofibroblasts, presumably in response to inflammation, is significantly enhanced.

Crohn’s disease runs a chronic relapsing and remitting course, with a significant disease-associated mortality rate of between 6% and 24% of patients observed within a 13- to 20-year follow-up (Cooke *et al.*, 1980; Farmer *et al.*, 1985; Trnka *et al.*, 1982). Crohn’s disease responds to immunosuppressive medications and antiinflammatory agents, although as yet no curative therapy has been found. Several case studies showing long-term remission from Crohn’s disease following autologous (Kashyap and Forman, 1998; Soderholm *et al.*, 2002) or allogeneic BM transplantation (Lopez-Cubero *et al.*, 1998; Talbot *et al.*, 1998) have been documented. Prior to BM transplant, a patient’s own BM is eradicated, and it is therefore possible that the observed remission of Crohn’s disease following BM transplant is due to the elimination of aberrant BM cells that play a critical role in the pathogenesis of Crohn’s disease. Furthermore, no immunosuppressive medication is required following BM transplantation in Crohn’s disease patients, indicating that the observed long-term remission is a direct result of the transplantation procedure (reviewed in James, 1998). We now suggest a possible mechanism by which BM cells provide remission from Crohn’s disease, by their formation of mesenchymal and vascular lineages in the inflamed colon, thereby contributing directly to tissue regeneration.

### I. INTRODUCTION

Currently, two conventional strategies are aimed at replacing absent or severely damaged portions of the alimentary tract. The first approach attempts to substitute native tissue with autogenous tissue derived from another anatomic location. For example, in cases of congenital long-gap esophageal atresia, the esophagus can be reconstructed using portions of stomach, colon, or jejunum. Similarly, the distal small intestine can be reconstructed into a colonlike pouch after removal of the large intestine. Unfortunately, these replacement tissues do not completely mimic the functions of the native tissue and therefore often result in poor function while incurring substantial donor site morbidity.

A second approach to replacing gastrointestinal tissue is through the transplantation of an entire organ from one person to another. This strategy is now a reasonable and potentially lifesaving option for carefully selected patients with intestinal failure. However, transplantation remains severely limited by the morbidity associated with immune rejection and chronic immunosuppression. Moreover, the continued shortage of available donor organs continues to be a major problem in the field of transplantation in general. As a result, transplantation can be justified only in selected clinical situations associated with high mortality, such as in cases of short bowel syndrome with recurrent sepsis.

Since the mid-1980s, a third approach to reconstructing the alimentary tract based on the principles of tissue engineering has emerged as another potential treatment option (Vacanti, 1988, 2003). Recently, tissue engineering has made significant progress in terms of successfully recapitulating all major structures within the alimentary tract. To date, esophagus, stomach, small intestine, and large intestine have all been created experimentally using the methods of tissue engineering. Despite significant challenges unique to the fabrication of the alimentary tract, ongoing work suggests enormous therapeutic potential in the years to come.

The purpose of this chapter is to provide an overview of the principles and current status of alimentary tract tissue engineering. We discuss the basic anatomy and physiology relevant to the field and review the rationale for tissue engineering as replacement therapy for severely damaged or absent alimentary tract tissue. We then evaluate the different state-of-the-art tissue-engineering strategies that have been employed in recent years using natural as well as synthetic scaffolds. Avenues for further exploration are also proposed.

### II. TISSUE-ENGINEERED SMALL INTESTINE

The native small intestine, which is composed of duodenum, jejunum, and ileum, is the most critical portion of the gastrointestinal tract. It is a remarkably complex and unique organ because of its digestion and vectorial trans-

port (i.e., absorption and secretion) capabilities. From the pylorus to the ileocecal valve, the adult small intestine measures approximately five to six meters in length. The pancreas and liver secrete important digestive juices into the duodenum to help facilitate the breakdown of food (Brunnicardi *et al.*, 2004).

The digestion and absorption capacity of the small intestine is facilitated by its highly specialized columnar epithelium, which features microscopic, fingerlike projections, known as *villi*, that help to increase total surface area. Brush border enzymes facilitate the digestion of carbohydrates as they are absorbed. In addition, each villus contains a lacteal and capillaries. The lacteal absorbs the digested fat into the lymphatic system, whereas the capillaries absorb all other digested nutrients. By the time the remaining products have reached the end of the small intestine, almost all nutrients and 90% of the water have been absorbed.

The smooth muscle layers of the small intestine are well organized and consist of an inner circular layer and an outer longitudinal layer. Intestinal smooth muscle helps to initiate antegrade propulsion of luminal contents (peristalsis). Both muscle layers are innervated intrinsically by autonomic nerve fibers and extrinsically by vagal and sympathetic nerve fibers. The celiac and superior mesenteric arteries provide essential arterial blood flow to the entire small intestine. The organ is a rich source of regulatory peptides, including secretin, cholecystokinin, and somatostatin, which are important for the control of various aspects of gut function. The mucosal immune system within the small intestine is critically important for defense against toxic and pathogenic threats from the luminal environment (Brunnicardi *et al.*, 2004).

Major surgical resection of small intestine is required in a variety of pediatric and adult disorders, including necrotizing enterocolitis, gastroschisis, midgut volvulus, and Crohn's disease. When less than 25% of the native small intestine is left, the remaining intestine cannot absorb all of the necessary calories (energy) required for survival. This leads to a state of malabsorption, malnutrition, and dehydration known as the *short bowel syndrome* (SBS). Intestinal adaptation can occur within the remaining native intestine. Unfortunately, these adaptive changes can take up to two years to occur and may not be enough to help the most severe cases of SBS.

The current mainstay of therapy for severe SBS, which was uniformly lethal until the late 1960s, is total parenteral nutrition (TPN). TPN is delivered through a central intravenous catheter and provides essential calories, vitamins, and minerals. Although this therapy has markedly improved survival rates, the costs of TPN can be prohibitive, and complications resulting from long-term intravenous access, including catheter sepsis, venous thrombosis, and liver failure, are common (Gupte *et al.*, 2006).

Given the high morbidity and mortality associated with SBS, a variety of interesting and often-innovative intestinal

operations have been developed over the years. These procedures include the tapering enteroplasty, intestinal valve placement, Bianchi procedure, and, more recently, the serial transverse enteroplasty (STEP procedure). All of these operations are designed to slow intestinal transit and/or increase intestinal surface area. Unfortunately, most of these techniques have since been abandoned, and no single approach with demonstrable long-term results has been reported in a large series of patients (Gupte *et al.*, 2006). Small intestinal transplantation is becoming a more realistic option in carefully selected patients (Abu-Elmagd, 2006). However, one-year graft survival rates are still far below those with other organs, and problems associated with rejection, immunosuppressive therapy, and donor organ shortages are not likely to be solved, at least in the near future.

### Early Studies Using Synthetic Scaffold-Based Approaches

In the 1980s, early studies were established that laid the groundwork for modern tissue engineering of small intestine. Thompson (1987) published the first report on the use of an absorbable biomaterial, polyglycolic acid (PGA), as a scaffold for the ingrowth of intestinal neomucosa. In a leporine model, he repaired ileal defects with PGA, Dacron, or PTFE. At eight weeks, minimal (15%) neomucosal development was present over each of these materials. Interestingly, Thompson was so discouraged by his results that he concluded that "the use of prosthetic materials is not likely to be used in the clinical management of short bowel syndrome."

Shortly after publication of this study, our laboratory, in collaboration with Robert Langer's group, began initial efforts to create tissue-engineered small intestine using cells transplanted onto biodegradable prosthetic materials. In the seminal study, fetal rodent intestine was enzymatically digested in collagenase, and the resulting enterocytes were seeded onto biodegradable polymers of polyglactin 910, polyandhydrides, and polyorthoester (Vacanti *et al.*, 1988). After four days in culture, the cell-polymer constructs were implanted into the omentum, interscapular fat pad, or mesentery of syngeneic adult hosts in order to facilitate neovascularization. After seven days in this *in vivo* bioreactor, microscopic examination of these implants revealed well-differentiated epithelium contained within a cystic structure. The cells retained their polarity and appeared to be secreting mucus, suggesting ongoing specialized function. From these results, we concluded that tissue-engineered small intestine was potentially feasible and was therefore worthy of further study.

In an effort to increase the efficiency of producing small intestinal neomucosa, subsequent work by Organ in our laboratory was aimed at isolating pure populations of intestinal crypt stem cells (Organ *et al.*, 1992). This approach is based on the premise that enterocytes represent a rapidly renewing cell population characterized by continuous

growth and differentiation. Using a method to isolate separate fractions of villus tip cells and crypt cells without the *in situ* leukocytes or fibroblasts, Organ showed that these intestinal crypt cells could be reliably isolated and used to reconstitute an epithelial layer on PGA scaffolds. However, the implanted constructs consistently demonstrated stratified epithelium five to seven layers thick. This mucosa was reminiscent of fetal gut development rather than that of normal columnar epithelium seen with mature small intestinal mucosa. In addition, no goblet cells or villus formation suggestive of advanced cellular or architectural differentiation was observed by 28 days *in vivo*. Based on these data, we concluded that this intestinal stem cell technique, as currently practiced, was limited by the absence of epithelial–mesenchymal cell–cell interactions, thought to be critical during embryonal organogenesis (Patel *et al.*, 1996).

### Synthetic Scaffold-Based Approaches Using Organoid Units

The use of organoid units, which preserve the important epithelial–mesenchymal interactions between cells as intestinal tissue is reconstituted, represents a major advance in small intestinal engineering. These unique cell clusters, termed *epithelial organoids*, were first described by Evans and Potten in the early 1990s in an attempt to establish primary cultures of intestinal cells (Evans *et al.*, 1992). In their initial study, the investigators found that a limited enzymatic digestion of neonatal rat intestine using a crude mixture of collagenase XI and dispase produced multicellular aggregates within a villus core composed of functional epithelial cells, mesenchymal tissue, and perhaps intestinal stem cells (Fig. 46.1). Approximately 50,000 organoid units, each approximately 100–200 microns in diameter, could be isolated per neonatal rat intestine. *In vitro* culture of these organoids has been demonstrated for up to 14 days.

In subsequent experiments, these small intestinal organoid units were used to regenerate small intestine–like structures *in vivo* in the absence of biodegradable scaffolds. This was first demonstrated when organoid units were implanted subcutaneously in a rodent model (Tait *et al.*, 1994a). Tait and Evans then showed that these organoid units could be used to regenerate a neomucosa with typical small bowel morphology and digestive enzyme activity when seeded onto the mucossectomized large intestine of adult rats (Tait *et al.*, 1994b, 1995). In contrast, control large intestine that underwent a mucossectomy without organoid implantation showed no epithelial regrowth. More recently, in an attempt to develop a treatment for bile acid malabsorption, Stelzner and his colleagues have transplanted organoid units derived from rat ileum onto denuded segments of jejunum and have shown increased bile acid uptake as well as increased ileal bile acid transporter protein expression within a neoileal segment (Avansino *et al.*, 2005).

The successful seeding of small intestinal organoid units on biodegradable scaffolds was first demonstrated by

**FIG. 46.1.** Transverse section through isolated small intestinal epithelial organoid units derived from a neonatal rat after hematoxylin and eosin staining (bar, 35  $\mu$ m). Integrity between the epithelial cell compartment and the underlying stromal core of lamina propria is maintained. From Tait *et al.* (1994a), p. 94.

Choi in our laboratory. In her initial work, organoid units derived from neonatal rat intestine were seeded on non-woven PGA tubes. Each tube was highly porous (e.g., 95%) and had a mean pore size of 250 microns to accommodate the size of these cell clusters (Choi and Vacanti, 1997). The outer surface of the scaffold was sprayed with 5% poly-L-lactic acid to help increase the resistance to compressional forces that would otherwise lead to luminal collapse after implantation. During the final step in the scaffold fabrication process, the tubes were coated with collagen type I to enhance organoid unit attachment (Fig. 46.2). The seeded constructs were then implanted into the omentum of syngeneic adult rats to allow for vascular ingrowth. As early as two weeks after implantation, the harvested constructs resembled cysts lined by a neomucosa composed of columnar epithelium with goblet cells and Paneth cells (Fig. 46.3). In addition, immunohistochemical staining for smooth muscle  $\alpha$  actin was positive in the stroma adjacent to the neomucosa, suggestive of the appropriate reconstitution of an intestinal smooth muscle layer (Fig. 46.4). Using an S100 stain, neuronal cells have also been detected in these constructs. Immunofluorescent staining of the neomucosa revealed the apical expression of brush border enzymes as well as basolateral staining for laminin (Choi *et al.*, 1998). Ussing chamber studies of the engineered constructs have shown a similar decreased active transepithelial resistance when compared to native small intestine, thus fulfilling major functional criteria for intestinal epithelia. Therefore, for the first time these studies established a reliable approach for generating tissue on biodegradable scaffold.

**FIG. 46.2.** (A) Gross appearance of a tubular scaffold composed of polyglycolic acid (PGA) and sprayed with 5% polylactic acid. folds that had a striking resemblance to native, full-thickness small intestinal mucosa.

Over the ensuing years, our laboratory has explored the organoid approach to engineering small intestinal cysts in considerable detail. Prolonged *in vitro* culture of these cells for days to weeks has not led to better results when compared to implantation within hours of organoid unit isolation. However, other modifications in this protocol have proven to be successful in creating more robust intestinal neomucosa. For instance, both side-to-side and end-to-end anastomosis of engineered intestine with native jejunum improve the histology within these cysts when harvested in

**FIG. 46.4.** Hematoxylin- and eosin-stained photomicrograph of rat tissue-engineered small intestine at 10 weeks after small bowel resection and side-to-side anastomosis (original magnification,  $\times 80$ ). L, cyst lumen; SM, smooth muscle. From Kim *et al.* (1999b), p. 11.

rodents up to 10 weeks postoperatively (Fig. 46.5) (Kaihara *et al.*, 1999a, 1999b; Kim *et al.*, 1999). Increased regenerative stimuli induced by small bowel resection, and to a lesser extent portacaval shunting, have also been shown to enhance the formation of tissue-engineered intestine in morphometric analyses. These results suggest a possible role for trophic factors such as hepatocyte growth factor (HGF) and epidermal growth factor (EGF) in neomucosal growth (Kim *et al.*, 1999). Patency of these engineered intestinal grafts has been maintained for up to 36 weeks (Kaihara *et al.*, 2000). Through ongoing collaboration with Whang and his colleagues, we have been able to further characterize the degree of angiogenesis and lymphangiogenesis within these tissue-engineered grafts (Gardner-Thorpe *et al.*, 2003; Duxbury *et al.*, 2004).

**FIG. 46.5.** (A) Gross appearance of rat tissue-engineered small intestine after side-to-side anastomosis to native small intestine at the time of harvest (black arrow denotes tissue-engineered small intestine). (B) Cross-sectional view of the patent anastomosis between the tissue-engineered construct and native small intestine (bar, 5 mm). From Kim *et al.* (1999b), p. 9.

Using a slight modification of the organoid unit isolation protocol, our laboratory has recently shown that these intestinal cysts, when anastomosed in a side-to-side fashion to native intestine after an 85% recipient enterectomy, can slow intestinal transit times and improve weight gain when compared to rats that had an enterectomy without tissue-engineered replacement (Grikscheit *et al.*, 2004). These data suggest that tissue-engineered intestinal cysts measuring as little as 10% of the length of native small intestine may be enough to provide adequate absorptive function in a rat model. In light of these promising results, we have initiated some large-animal studies using the organoid unit approach

**FIG. 46.6.** Hematoxylin- and eosin-stained photomicrograph of tissue-engineered small intestine harvested from the omentum after seven weeks in a juvenile porcine model (original magnification,  $\times 200$ ). Unpublished data, courtesy of Tracy C. Grikscheit and Erin R. Ochoa.

and have since demonstrated successful generation of tissue-engineered small intestine in a juvenile porcine model (Fig. 46.6, previously unpublished).

Engineered intestinal cysts have also provided a unique experimental model system for the study of intestinal morphogenesis. For example, in anastomosed tissue-engineered small intestinal cysts harvested at 20 weeks, the density and topographical distribution of immune cell subsets, namely T-cells, B-cells, and NK-cells, were found to be identical to those of normal jejunum (Perez *et al.*, 2002). Furthermore, these immunocyte population densities were only rudimentary in nonanastomosed cysts. These findings imply that exposure to luminal stimuli may be critical to the formation of a mucosal immune system.

It has also been shown that anastomosis of intestinal cysts to native intestine enhances expression of the sodium-dependent glucose transporter, SGLT1 (Tavakkolizadeh *et al.*, 2003). Mucosal growth and SGLT1 expression can also be augmented in this model if rats are given glucagon-like peptide 2 (GLP-2), an endogenous regulatory peptide that has potent trophic activity specific for intestinal mucosa (Ramsanahie *et al.*, 2003). Third-generation biomaterials, which can be designed for the controlled release of substances embedded with the biodegradable scaffold, have been used in other tissue-engineering applications and may be an approach to generate more robust intestinal neomucosal growth in our model (Kent Leach *et al.*, 2006).

Although organoid units have been highly successful in regenerating features of native small intestinal mucosa, it is important to realize the limitations of this strategy as it

is performed currently. For example, despite the use of tubular scaffolds based on PGA, these intestinal constructs form not cylindrical tubes but, rather, oblate spheroids reminiscent of intestinal duplication cysts. This phenomenon occurs, at least in part, because of the increased intraluminal pressure as the intestinal neomucosa regenerates and produces secretions. Additionally, PGA clearly does not have adequate mechanical strength to withstand the increased intraluminal pressure, despite a degradation time of approximately six weeks. Regardless, the resultant oblate spheroid architecture suggests that meaningful and coordinated peristalsis within a sizable construct is unlikely, even in the presence of an innervated smooth muscle layer. Methods to decompress the lumen during the process of intestinal epithelial regeneration may be helpful in producing a more desirable architecture. In addition, the use of novel biomaterials that have more favorable mechanical and degradation characteristics may allow for better control of the three-dimensional geometry of neointestine. Studies utilizing alternative scaffolds, such as poly(epsilon-caprolactone) (PCL) and poly(ester urethane)urea (PEUU), remain ongoing in our laboratory, and the early data are promising.

Another limitation of the organoid unit approach to creating tissue-engineered small intestine is the inability consistently to expand these cell clusters *ex vivo*, as was originally described by Evans and colleagues. At present, a relatively high number of organoid units (approximately 15,000 cm<sup>2</sup>) are required to create an intestinal construct using the omentum as an *in vivo* bioreactor. Unfortunately, we have been unable to culture normal organoid units for more than a week *in vitro*. Transformed epithelial cell lines could technically be used for small intestinal tissue engineering but are not desirable, since they are neither autologous nor normal epithelial cells.

An intriguing variation of the organoid unit approach to small intestinal tissue engineering was recently reported by Lloyd and his group in Britain (Lloyd *et al.*, 2006). In this study, they implanted tubular poly-lactide-co-glycolide (PLGA) foam scaffolds subcutaneously into rats. The PLGA had a thickness of 2 mm and was supported by inner silicone tubing. After five weeks, the silicone tubing was removed, and the lumen was filled with intestinal organoid units suspended in a hydrogel containing HGF. All constructs that were examined four weeks later revealed spheroid cysts with evidence of intestinal mucosa within the lumen. A potential benefit of this approach is the apparent efficiency by which neomucosa can be generated from a given sample of donor tissue. Nevertheless, there are a number of confounding factors (e.g., hydrogel, growth factor administration) that may also explain the positive results in this study. It remains unclear whether any smooth muscle was present in these constructs at harvest. Furthermore, as we have already discussed, the overall spherical architecture of these engineered intestinal grafts remains less than ideal.

## Natural Scaffold Approaches in Intestinal Engineering

Some groups have explored different methods for creating tissue-engineered intestine using acellular, natural scaffolds. Unfortunately, these results have generally been more mixed. Small intestinal submucosa (SIS), an extracellular matrix material derived from porcine small intestine, has been a biomaterial preferred by a number of investigators. For example, Chen and colleagues have repaired partial and full circumferential defects in the small intestine using either single-layer or multilayered SIS in a canine model (Chen and Badylak, 2001). None of these scaffolds was seeded with isolated cells prior to implantation. Evaluation of the partial circumferential repairs showed no luminal narrowing when followed for up to one year postoperatively. Histology at later time points demonstrated layers of remodeled wall containing a mucosal epithelium as well as varying amounts of smooth muscle and collagen that resembled native small intestine. Unfortunately, all dogs that received a tubular segment of SIS placed as an interposition graft had significant problems, including obstruction and anastomotic leak.

The use of SIS as an interposition graft in an ileal loop rodent model has been reported by Wang and colleagues (2003). This group used a four-ply layer of SIS without any cell seeding and experienced minimal complications with this material. However, up to 40% graft shrinkage was observed when rats were followed out to 24 weeks postoperatively. Histologically, mucosal ingrowth of intestinal epithelium was present, although the smooth muscle layer was less organized, and no neuronal cells have been demonstrated to date (Fig. 46.7) (Wang *et al.*, 2005). Recently, Dunn and his colleagues reported their experience with SIS after duodenotomy in a rodent model and observed complete epithelialization of a 6-mm-diameter defect by four weeks postoperatively (De Ugarte *et al.*, 2004). Unfortunately, the muscularis layer was notably absent in all examined specimens.

Collagen is another natural scaffold that has been used in small intestinal tissue engineering. In a canine model, Hori and colleagues resected a portion of jejunum and reconstructed the intestine using an acellular collagen sponge supported by a silicone stent (Hori *et al.*, 2001). Small intestinal epithelium was present overlying these grafts at harvest, but no muscle layer was present. In follow-up studies, cell seeding of the collagen sponge with gastric smooth muscle cells, but not bone marrow-derived mesenchymal stem cells, seemed to induce long-term formation of smooth muscle layer beneath the intestinal epithelia (Hori *et al.*, 2002; Nakase *et al.*, 2006).

## III. TISSUE-ENGINEERED ESOPHAGUS

The esophagus, which measures 25 cm in length in adult males, starts as a continuation of the pharynx and

**FIG. 46.7.** Hematoxylin- and eosin-stained photomicrographs of rat small intestine generated on small intestinal submucosa (SIS). **(A)** No epithelialization at the luminal surface by two weeks. Arrows depict neovascularization. **(B)** Major portion of the epithelialized graft luminal surface by eight weeks. Inflammatory reaction was minimal. **(C)** A well-organized mucosal epithelial layer with smooth muscle cells regeneration has occurred at three months. **(D)** A well-developed mucosa, smooth muscle, and serosa of the regenerated bowel wall in another animal (original magnification,  $\times 100$ ). From Wang *et al.* (2003), p. 1598.

ends at the cardia of the stomach. Its blood supply is derived from other organs in the neck, chest, and abdomen. The esophagus resembles a muscular tube lined with nonkeratinizing squamous epithelium. Scattered submucosal mucus glands provide lubrication. The muscularis layer plays a vital role in the peristaltic propulsion of food, such that both solids and liquids can enter the stomach even when being turned upside-down. As with all portions of the alimentary tract, the nerve supply of the esophagus is both parasympathetic and sympathetic. A rich network of intrinsic ganglia within the submucosa and muscularis provides essential innervation. The upper one-third of the esophagus is composed predominantly of striated (voluntary) skeletal muscle. In the lower third, the esophagus contains only smooth (involuntary) muscle. At the junction of the esophagus and

stomach is a sphincter valve that provides a physiologic barrier between the two organs. As the food approaches the closed ring, the surrounding muscles relax and allow the passage of food.

There remains considerable interest in the creation of tissue-engineered esophagus for the treatment of a wide range of pathologies. Unlike the rest of the gastrointestinal tract, the esophagus has little redundancy, thereby leaving little autologous esophageal tissue available for reconstruction. In neonates born with long-gap esophageal atresia, the esophagus is commonly repaired by placing a segment of colon into the chest from the upper pouch to the lower pouch, based on its own vascular supply. Although this procedure has been successful, long-term complications, including anastomotic leak, stricture, dysmotility, and

malignant transformation, are not uncommon (Ure *et al.*, 1995). Esophageal reconstruction after chemical injury or cancer has also been fraught with similar complications.

Initial attempts at creating a replacement esophagus used artificial materials, including rubber, polyethylene, Teflon (PTFE), and polypropylene, among others (Sato *et al.*, 1997). Most of these materials were eventually extruded and served as poor scaffolds to facilitate tissue ingrowth. Furthermore, major complications, such as anastomotic leak and stenosis, were a common occurrence. Autologous tissue and homografts, including skin, trachea, and fascia, have been used as esophageal substitutes, with minimal success (Sato *et al.*, 1997).

### Collagen-Based Scaffold Approaches

One of the early studies of bioprosthetic esophageal replacement was reported by Takimoto and colleagues (1993). In this study, they created a 5-cm cervical esophageal defect in a canine model. The defect was then repaired using a two-layered tube consisting of a collagen sponge matrix (composed of types I and III) and an inner silicone stent. The stent was subsequently removed endoscopically at two to four weeks postoperatively. After stent removal at four weeks, regenerated esophageal tissue was found at the site of the defect, and all dogs were able to tolerate oral feeding. Histologically, there was regeneration of host-derived tissue within the collagen sponge, as shown by stratified squamous epithelia and striated muscle, complete with an inner circular and an outer longitudinal layer.

In a follow-up study, the same prosthesis was used to repair a 5-cm thoracic defect (Yamamoto *et al.*, 1999). At the time of stent removal, the host-regenerated tissue had replaced the gap in all dogs, and the mucosa had fully regenerated at three months. Some mild stenosis and shrinkage did occur, but not after three months postoperatively. The muscularis mucosa was seen as islets of smooth muscle by 12 months. Unfortunately, many of these grafts were quite thin, and muscle did not extend into the middle of the regenerated segment. This observation may have been due to the relatively poor blood supply in the mediastinal region of the esophagus. However, increasing blood vessel ingrowth into these grafts using either an omental wrap or basic fibroblast growth factor has not led to substantially improved results (Yamamoto *et al.*, 2000; Hori *et al.*, 2003). More recently, this collagen sponge technique was used after circular myotomy of the esophagus and may promote healing by facilitating connective tissue ingrowth (Komuro *et al.*, 2002).

One cell-based strategy using collagen scaffolds has seeded these constructs with cultured keratinocytes (Sato *et al.*, 1994; Hayashi *et al.*, 2004). In one variation of this approach, Sato and colleagues isolated keratinocytes from rodent esophageal biopsies and expanded these cells *ex vivo* in growth medium. The cells were subsequently seeded onto collagen type I gels that were embedded with dermal

fibroblasts and smooth muscle cells derived from the same donor (Hayashi *et al.*, 2004). The sheets were then transferred onto PGA mesh or porcine dermis prior to implantation into the latissimus dorsi muscle of athymic rats. Using this multilayered approach, the investigators have been able to demonstrate a fairly complex esophageal construct containing the major components of native esophagus, including smooth muscle (Fig. 46.8). The tubular architecture has been maintained *in vivo* using PGA. Unpublished data from Sato has shown that these grafts can be rolled over silicone tubes and anastomosed to rat jejunum in an end-to-end fashion.

### Submucosal Scaffold-Based Approaches

Acellular scaffolds such as porcine-derived SIS and urinary bladder submucosa have been used in several canine models of esophageal repair (Fig. 46.9) (Badylak *et al.*, 2000, 2005). In his initial series, Badylak and colleagues (2000) created full-thickness lesions in the cervical esophagus in dogs and repaired these defects with SIS. After several weeks, all of the scaffolds were replaced by skeletal muscle, which was oriented appropriately and was contiguous with adjacent normal esophageal skeletal muscle (Fig. 46.10). In addition, there was an intact squamous epithelium derived from host migration of epithelium. Unfortunately, a major limitation to the use of these acellular scaffolds in esophageal-tissue engineering has been the problem of stricture, which occurs at a much higher frequency after repair of full circumferential defects.

**FIG. 46.8.** Hematoxylin- and eosin-stained photomicrograph showing rat tissue-engineered esophagus using keratinocytes seeded onto a collagen gel containing fibroblasts (original magnification,  $\times 100$ ). From Fuchs *et al.* (2001), p. 586.

**FIG. 46.9.** Photograph of a single-layer sheet of decellularized porcine submucosa used for esophageal reconstruction in a canine model. From Badylak *et al.* (2005), p. 89.

**FIG. 46.10.** Masson trichrome-stained photomicrograph demonstrating near-complete remodeling of the extracellular matrix (ECM) scaffold with neoesophageal tissue after five months in a canine model (original magnification,  $\times 120$ ). There is an intact squamous epithelium, a submucosal layer that is focally devoid of glandular elements, and bundles of partially organized skeletal muscle. From Badylak *et al.* (2000), p. 1100.

### Synthetic Scaffold-Based Approaches

Grikscheit, from our group, has demonstrated the feasibility of the organoid unit approach in esophageal-tissue engineering (Grikscheit *et al.*, 2003). Applying the same collagenase/dispase digestion technique used to produce small intestinal organoid units, esophageal organoid units were successfully isolated from neonatal esophagus and labeled overnight with green fluorescence protein (GFP) to follow their long-term fate *in vivo*. The organoid units were subsequently seeded onto PGA/PLLA tubes and implanted in the omentum of syngeneic rats. After four weeks *in vivo*, histological evaluation revealed the formation of a complete

**FIG. 46.11.** Hematoxylin- and eosin-stained photomicrograph illustrating tissue-engineered esophagus in a rodent model based on esophageal organoid units (original magnification,  $\times 100$ ). From Grikscheit *et al.* (2003a), p. 539.

esophageal wall, including full-thickness stratified squamous mucosa, submucosa, and muscularis propria (Fig. 46.11). Neuronal innervation was not seen in any harvested specimens. The constructs were then used to replace the abdominal esophagus, either as an onlay patch or as an interposition graft. Postoperatively, all animals gained appropriate weight. Although gross inspection of these grafts at sacrifice seven weeks later revealed a massively dilated and cystic construct, there was no evidence of anastomotic leak or obstruction in any rat on fluoroscopy (Fig. 46.12). Long-term survival of the donor cells was demonstrated by maintenance of the GFP signal at harvest. Given the cystic characteristics of these esophageal constructs using PGA, ongoing studies are attempting to seed organoid units onto newer biomaterials with more favorable mechanical characteristics that would allow for maintenance of the tubelike architecture of the native esophagus.

## IV. TISSUE-ENGINEERED STOMACH

The stomach is a well-vascularized, short-term storage reservoir located in the left upper quadrant of the abdominal cavity. It receives ingested food from the esophagus and delivers it to the duodenum. Although the adult stomach has a volume of only 50 mL when empty, as the muscles of the upper portion of the stomach relax, approximately one liter of swallowed material can be accepted (Brunnicardi *et al.*, 2004).

Vigorous contractions produced by the muscular wall of the stomach within an acidic (pH 1–3) environment enable the breakdown of food. The stomach is also an

**FIG. 46.12.** Gross appearance of rat tissue-engineered esophagus (TEE) at harvest following end-to-end anastomosis with the native alimentary tract. The native esophagus (NE) is shown above the TEE. The stomach (S) is located distally and joins the duodenum (D). From Grikscheit *et al.* (2003), p. 543.

important site for the digestion of proteins. Chief cells, which secrete pepsinogen to aid in protein digestion, as well as parietal cells, which secrete hydrochloric acid, help to form a densely packed mucosa composed of simple, columnar epithelium. Intrinsic factor production by parietal cells is important for the absorption of vitamin B<sub>12</sub> in the ileum. Food is delivered slowly into the small intestine upon relaxation of the pylorus, a ringlike valve composed of smooth muscle (Brunnicardi *et al.*, 2004).

Gastric adenocarcinoma is one of the most common cancers worldwide. In Japan, gastric cancer afflicts approximately one in 1000 patients. For proximal gastric cancer, a total or near-total gastrectomy may be required for survival. Numerous gastric replacement techniques involving autologous jejunum have been used in an effort to improve the quality of life in these patients. Unfortunately, the morbidity associated with these procedures remains high, in part because intestinal substitutes cannot sufficiently recapitulate the specialized functions (i.e., acid secretion, enzymatic digestion, intrinsic factor secretion) of the native stomach. Significant morbidity is common and includes severe malnutrition, weight loss, reflux esophagitis, and anemia (Brunnicardi *et al.*, 2004). A tissue-engineered stomach would represent a significant advance toward improving clinical outcomes in these patients.

### Collagen Scaffold-Based Approaches

The earliest efforts to create a tissue-engineered stomach attempted to reconstruct the stomach wall using a collagen

**FIG. 46.13.** Immunohistochemical staining for gastric mucin in rat tissue-engineered stomach (original magnification,  $\times 200$ ). From Maemura *et al.* (2003), p. 63.

sponge scaffold in a canine model. With this approach, Hori and his colleagues (2001a) resected a 4  $\times$  4-cm portion of the anterior wall of the stomach and subsequently reconstructed the stomach using a collagen sponge scaffold reinforced with PGA felt. Omentum was sutured to the outer wall of the scaffold to facilitate vascular ingrowth, and a silicone sheet was left in place on the luminal side to protect the scaffold from degradation by digestive juices. After four weeks, the silicone sheet was removed. By 16 weeks, histological analyses revealed a highly organized layer of stomach mucosa overlying the collagen scaffold as well as evidence of a thin muscle layer. Unfortunately, a follow-up functional analysis using organ bath studies did not demonstrate any acetylcholine-induced contraction of the tissue-engineered stomach wall (Hori *et al.*, 2002b).

### Synthetic Scaffold-Based Approaches

Our group has employed the organoid unit approach to create tissue-engineered stomach in a rodent model (Maemura *et al.*, 2003, 2004; Grikscheit *et al.*, 2004). In these studies, gastric organoid units were isolated from both neonatal and adult donors and seeded onto PGA/PLLA tubes implanted into the omentum of syngeneic adult hosts. Three to four weeks later, the engineered constructs resembled cysts and showed well-developed gastric epithelium on histology. Well-formed basal gastric glands were also identified, and immunohistochemical staining demonstrated positive expression of gastrin and mucin within the mucosal lining (Fig. 46.13). A well-organized smooth muscle layer was also present. After anastomosis of tissue-engineered stomach to host native small intestine, the mucosal architecture within these constructs was maintained. In one of these studies, the native stomach was resected and the cephalad end of the tissue-engineered stomach was anasto-

**FIG. 46.14.** Upper gastrointestinal contrast study 10 minutes after barium injection after replacement of the native stomach with tissue-engineered stomach in rats. The white arrow points to the location of the tissue-engineered stomach. From Maemura *et al.* (2003), p. 63.

mosed to the native esophagus (Maemura *et al.*, 2003). At follow-up, there was no evidence of obstruction or stenosis after an upper gastrointestinal study (Fig. 46.14). Unfortunately, preliminary evidence has not shown a significant short-term improvement in weight gain when compared to control rats that underwent total gastrectomy with a Roux-en-Y reconstruction. Thus, the functionality of the tissue-engineered stomach remains to be determined.

## V. TISSUE-ENGINEERED LARGE INTESTINE

The distal portion of the alimentary tract, known as the large intestine or colon, extends from the cecum to the rectum. The large intestine has a much larger caliber than the small intestine but measures only 1.5 meters in length. The primary function of the colon is to store waste and to reclaim any remaining water that is not absorbed by the small intestine. The ileum expels approximately 1500 mL of fluid per day, of which 1350 mL is absorbed by the colon. Digestion is an underrecognized activity of the large intestine. Primarily anaerobic bacteria within the colon have the ability to ferment proteins, dietary fiber, and carbohydrate. After the colon has processed all the material received by the ileum, its contents are propelled into the rectum as feces, where it remains until expelled during a bowel movement (Brunnicardi *et al.*, 2004).

The large intestine is lined with simple columnar epithelium without villi or Paneth cells. Unlike the small intestine, the longitudinal muscle of the colon forms three dominant cables of muscle, called *taenia coli*, that originate in the cecum and fuse together to form a circumferential coat at the junction of the sigmoid colon and

**FIG. 46.15.** Hematoxylin- and eosin-stained photomicrograph of rat tissue-engineered large intestine (original magnification,  $\times 100$ ). From Grikscheit *et al.* (2003b), p. 38.

rectum. The major blood supply of the large intestine is derived from both the superior and inferior mesenteric arteries. As in other areas of the alimentary tract, the large intestine is innervated via the sympathetic and parasympathetic nervous systems.

There are some clinical conditions, such as ulcerative colitis, familial adenomatous polyposis, and long-segment Hirschsprung's disease, in which a total colectomy (i.e., removal of the entire colon and rectum) is required for survival. Although an ileal pouch can provide some restorative function in these patients, no reliable replacement therapy for the native large intestine currently exists. Post-colectomy morbidities, including high stool frequency, pouchitis, and pelvic sepsis as a result of pouch leak, can be significant and debilitating for patients (Meagher *et al.*, 1998). The cumulative frequency of pouchitis at major referral centers approaches 50% over 10 years. Therapy directed at relieving pouch morbidity includes revision or conversion to end-ileostomy, transrectal catheter drainage, antibiotics, and steroids (Fonkalsrud and Bustorff-Silva, 1999). Ileal mucosal adaptation in the pouch through colonic metaplasia and chronic inflammation has been postulated to increase long-term neoplasia.

To date, the organoid unit approach using PGA scaffolds has been the only reported strategy to create tissue-engineered large intestine. In our laboratory, Grikscheit used minced neonatal rat large intestine reliably to generate tissue-engineered large intestinal cysts (Grikscheit *et al.*, 2002). These grafts contained all of the histological elements of native large intestine, including long crypts of Lieberkuhn, goblet cells, and the presence of acetylcholinesterase within the lamina propria (Fig. 46.15). Ussing chamber data indicated *in vitro* function consistent with that of mature colonocytes, including a positive short-circuit current response to theophylline indicating intact ion transfer. Transmission

electron microscopy revealed normal microarchitecture. After anastomosis to native small intestine, colon morphology was preserved, and gross fluid absorption was noted *in vivo*.

In a follow-up study, the physiologic function of tissue-engineered colon as a replacement therapy was evaluated (Grikscheit *et al.*, 2003b). Rats received either endileostomies or engineered colon constructs, which were anastomosed in a side-to-side fashion 1 cm from the stoma. Transit times, as measured by phenol red gavage, were more than doubled in rats with tissue-engineered intestine when compared to controls. In addition, animals with tissue-engineered colon had a lower degree of weight loss, lower stool moisture content, high stool short-chain fatty acids, and higher total serum bile acids. These results suggest the real possibility that tissue-engineered large intestine may someday be a useful treatment in patients requiring proctocolectomy.

## VI. CONCLUSIONS

Since its inception approximately two decades ago, alimentary-tract-tissue engineering has been a vibrant field of study within regenerative medicine. Through the combined efforts of physicians, engineers, cell biologists, and others, remarkable progress has been made with regard to the fabrication of these relatively complex tissues. Using the organoid unit approach, we have gained a better understanding of intestinal morphogenesis and of other basic biological phenomenon, including epithelial regeneration, epithelial-mesenchymal interactions, cell-matrix interactions, and the role of different growth factors in intestinal development. For the first time, tissue-engineered small

intestine, esophagus, stomach, and large intestine can now be reliably created, with each of these engineered tissues containing all of the major histological components of full-thickness, native tissue. More importantly, preliminary studies of these tissue-engineered constructs are beginning to show evidence for physiological function in a number of animal models.

Nevertheless, we have also learned that re-creating the alimentary tract is not a simple task. Successful application of tissue-engineered gastrointestinal structures in humans requires overcoming many unique challenges. As a result, clinical application of engineered gastrointestinal tissues still remains a number of years away. Ongoing work must work to understand better how optimally to harvest the relevant cell populations and how to expand them either in monolayer culture or in three-dimensional culture systems. We must also learn more about how to build gastrointestinal structures composed of a dynamic and complex epithelial lining over a fully innervated muscular tube. It is likely that the resultant tissue also needs to be in the appropriate gross geometry in order to have adequate functional capacity for peristalsis. The use of more advanced biomaterials, as outlined in other chapters in this book, may be particularly helpful in this regard.

As with many scientific and medical endeavors, incremental and stepwise progress in alimentary-tract-tissue engineering is likely to continue, and we should remain excited and optimistic about its future. The increasing number of investigators worldwide that are currently engaging in this fascinating area of research is a testament to the promise of alimentary-tract-tissue engineering for the thousands of unfortunate patients in need.

### I. INTRODUCTION

The identification of liver stem cells would have two possible applications. In cell-based therapy, transplantation of liver stem cells could be an alternative to whole-liver transplantation for patients suffering liver dysfunctions. For liver cancers, the identification of liver cancer stem cells would result in novel anticancer therapies directed against cancer stem cells. The field of cell therapy and that of anti-cancer therapy are inextricably linked; understanding the biology of liver stem cells will benefit both fields greatly. This chapter is limited to liver-derived stem cells.

The issue of the presence of liver stem cells in adult liver remains controversial. This is partially due to the fact that the proliferation of adult hepatocytes, a well-differentiated cell, accomplishes regeneration of the liver after injury, with the capacity of self-renewal. Another reason why the issue of a liver stem cell is still contentious may be the lack of clear evidence of the liver stem cell's presence in the adult liver. This topic of liver stem cells has received more attention recently with the prospective identification of stem/progenitor cells in fetal liver. Here we review some recent evidence of the lineage organization of the liver and the value of the prospective isolation of a liver stem cell for regenerative medicine.

### II. DEFINITION OF A TISSUE-DERIVED STEM CELL

The classic definition of a tissue-derived stem cell comes from the study of hematopoietic stem cells. These stem cells have been defined as clonogenic cells capable of self-renewal and differentiation into multiple committed progenitor cells, which then proliferate and differentiate into functionally specialized mature cells (Bryder *et al.*, 2006). In the search for hematopoietic stem cells, which was driven by the need for bone marrow transplantation in patients, a hierarchy of blood-forming cells from primitive stem cells, committed progenies, and mature cells was uncovered (Till and McCulloch, 1961; Siminovitch *et al.*, 1963; Schofield, 1970, 1978; Spangrude *et al.*, 1988; Baum *et al.*, 1992). With the prospective isolation of hematopoietic stem cells (Spangrude *et al.*, 1988; Baum *et al.*, 1992), it was then possible to compare stem cells to all the other blood cells in the regenerative process of bone marrow transplantation. To the surprise of many, only the hematopoietic stem cells, and not the other more committed progenitor cells of the bone marrow, were able to sustain a long-term engraftment in animal models. Thus, in the context of bone marrow transplantation, only stem cells seemed to be important for

the sustained regeneration of the hematopoietic system. This is in part due to the foremost property a stem cell must have, the capacity for self-renewal. Cells without self-renewing potential, such as committed progenitor cells, will still be capable of generating enough progeny for a short-term engraftment but will not be capable of sustaining a long-term engraftment over many years. Therefore, self-renewal is a key function for stem cells.

Another property of stem cells is their multipotentiality. Stem cells are capable of producing progeny in more than one lineage. Again, the best-known example of a pluripotent tissue-derived stem cell is hematopoietic stem cells. Hematopoietic stem cells have the capacity to give rise to many lineages, from short-term stem cells to multipotent progenitor cells, to oligolineage progenitors to differentiated progenies (Bryder *et al.*, 2006). In this process, hematopoietic stem cells lose their self-renewal with functionally irreversible maturation steps. Finally, clonality is probably the ultimate proof of the presence of stem cells, because it allows one to demonstrate that both self-renewal and multipotent potential are present at the single-cell level. However, for stem cells to maintain their stemness, at least some of the cells must undergo division without differentiation while others differentiate.

Thus, any claim for the isolation and identification of a liver stem cell has one minimal requirement: the demonstration that a liver stem cell can be prospectively isolated and is a clonogenic cell, capable of self-renewal and differentiation to the expected lineages of the liver, namely the hepatocyte and bile duct lineages (see Fig. 47.1). In this chapter, we present a compilation of experiments published recently that support these assumptions.

### III. CELLULAR ORGANIZATION OF THE ADULT LIVER

The liver is one of the largest organs of the body. It can be considered an exocrine gland with glandular acinus, composed of hepatocytes, with draining ducts lined by bile duct cells. Both the bile duct cells (also called *cholangiocytes*) and the hepatocytes (also called *parenchyma cells*) belong to the same hepatic lineage with a common stem cell, the liver or hepatic stem cells (see Fig. 47.1). Within the acinus, also called the *hepatic lobule*, two distinct vascular beds are found: A set of six portal triads are present at the periphery of the acinus, composed of hepatic arteriole, portal venule, and a bile duct. The central vein is in the middle of the hepatic lobule. Blood enters the liver from the portal venule or hepatic arteriole and flows between liver sinusoids that have fenestrated endothelium toward the central vein. Thus, contact between blood and hepatocytes allows filtration of the blood. A bile canaliculus forms a channel adjacent to the hepatocytes and serves to drain secreted bile toward the bile duct of the portal triad. In addition to hepatocytes and bile duct cells, stellate cells (for-

merly called *Ito cells*), Kupffer cells (the macrophage of the liver), endothelial cells, fibroblasts, and leukocytes can present in significant numbers in the liver. Hepatocytes along the hepatic plate, from the portal triad to the central vein, present a display of heterogeneous biochemical properties as well as a pattern of gene expression.

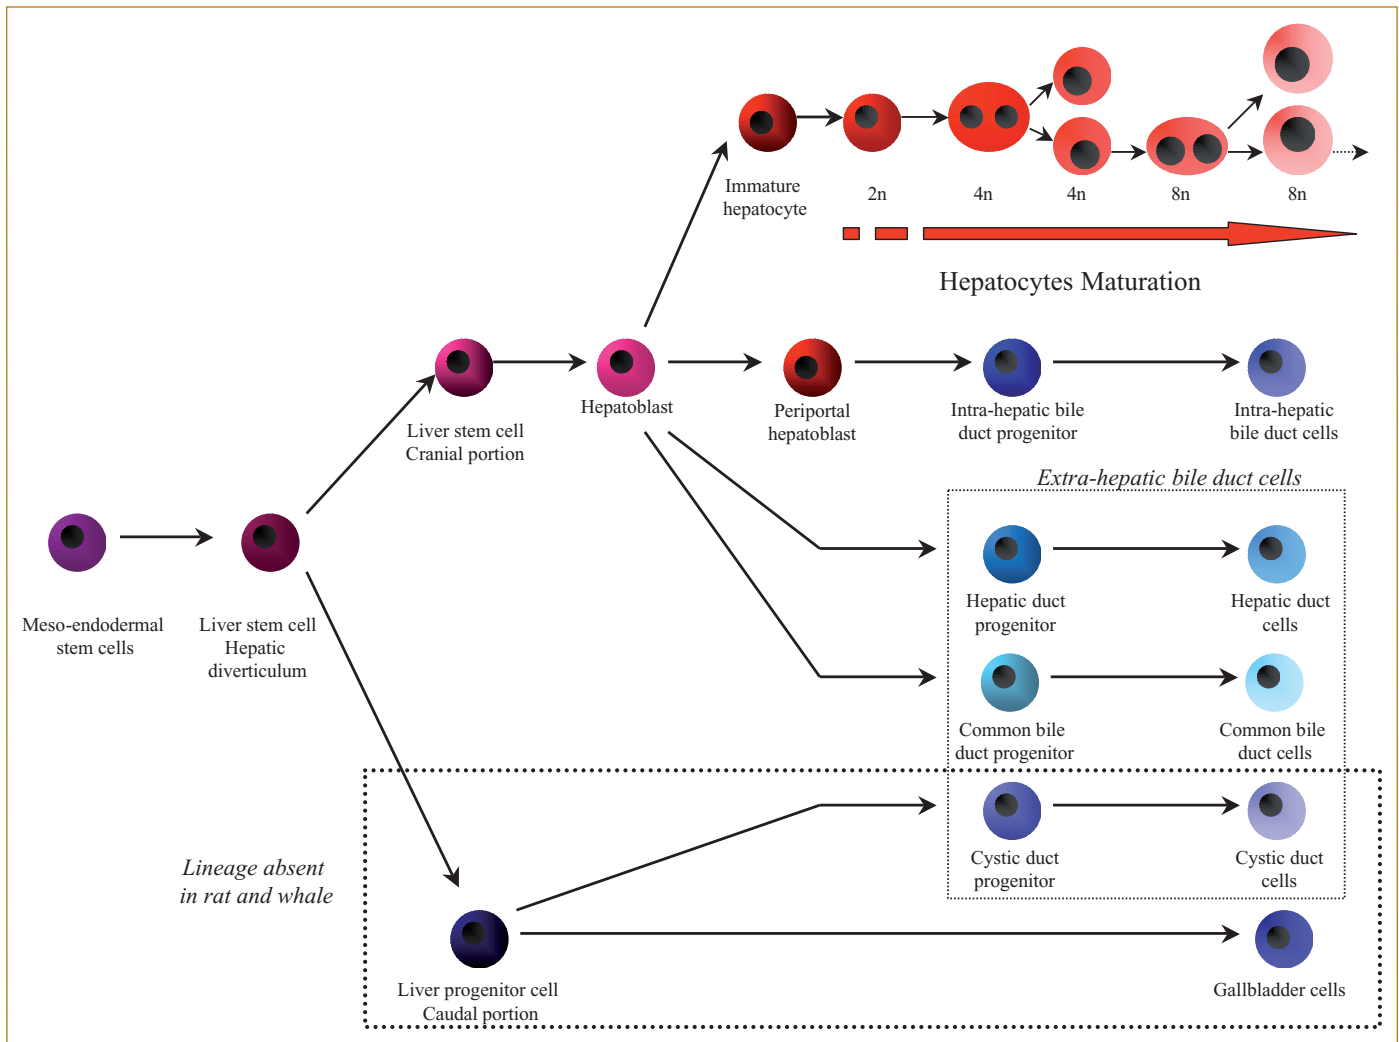

Different zonal locations have been distinguished. The periportal zone is where most of the primitive cells would reside. The canals of Hering, which represent the connection between the bile canaliculi and the bile duct, are in the periportal zone and have been proposed to be the site of liver stem cells. Then comes the mid-acinar zone and lastly the pericentral zone, adjacent to the central vein and presenting the more mature hepatocytes. Liver-specific gene expression with distinct patterns has been associated with different zones of the liver acinus. However, findings of alteration in gene expression after rerouting of the blood flow through the liver support the interpretation of regulated gene expression by microenvironment (Jungermann and Kietzmann, 1996).

## IV. HEPATOCYTES: THE FUNCTIONAL UNIT OF THE LIVER WITH STEM CELL PROPERTIES

### The Liver Is an Amazing Organ Because It Can Regenerate

Centuries ago, the Greek myth of Prometheus told of the mortal who stole fire from Zeus and was punished by having his liver devoured by an eagle at dusk, only to have it regenerated by next morning. Even though the myth exaggerated the regenerative potential of liver, this phenomenon was recognized much later in medicine, with some the early scientific reports in the literature coming from Germany and England. The classic experiment by Higgins and Anderson (1931) demonstrated experimentally that surgical removal of two-thirds of a rat liver was possible without significant mortality and, more importantly, resulted in regeneration of the remaining lobes of the liver in five to seven days by compensatory hyperplasia.

Serial surgical resection of the liver (hepatectomy) in experimental animals is possible, resulting each time in the extraordinary compensatory growth of the remaining liver lobes, suggesting that this extraordinary regenerative potential of the liver may be due to liver stem cells. This model of hepatectomy has been intensively studied and to the surprise of many is not dependent on liver stem cells. In contrast to other regenerative tissues, such as bone marrow and gut, mature cells, mostly hepatocytes, in response to stimuli like growth factors, will enter into a cell cycle and drive liver regeneration. Hepatocytes were shown to be the main proliferating cell responsible for the regrowth of the liver, because they are the most abundant epithelial cells of the liver (~60%), representing most of the mass of the organ due

**FIG. 47.1.** Model of the hepatic lineage in the mammalian system. Based on the review by Shiojiri (1997). Gallbladder and cystic duct do not develop through hepatic development in the rat and whales.

to their large size. Hepatocyte proliferation will start in the periportal region and will spread to the centrilobular region. In general, the regeneration of the liver mass required each hepatocyte to undergo an average of 1.4 rounds of replication to restore the liver mass. However, other type of cells are also involved in the process of liver regeneration, including biliary epithelial cells, hepatic stellate cells (found in the space of Disse, juxtaposed between hepatocytes and liver sinusoids), endothelial cells lining sinusoids, fibroblasts, and Kupffer cells (see the review by Michalopoulos and DeFrances, 1997).

### Hepatocyte Transplantation: The “Proof-of-Concept” to Cell-Based Therapy for Liver Disease in Animal Models

Our understanding of the potential of cell-based therapy for liver disease has come from studies of transplanted liver cells in animal models. The first experiments described

transplantation and survival of hepatocytes in spleen (Mito *et al.*, 1979). This work was followed by the demonstration that these ectopic hepatocytes were functional and could proliferate (Darby *et al.*, 1986; Selden *et al.*, 1986; Gupta *et al.*, 1987). Hepatocyte transplantation has been used in experimental animal models with inherited metabolic liver diseases (Matas *et al.*, 1976; Groth *et al.*, 1977). These experiments have established that allotransplantation of normal hepatocytes and autotransplantation of genetically modified hepatocytes can correct metabolic defects.

More recently, the use of transgenic and knockout mice provided excellent models of liver regeneration from cell transplantation. In these models, inherited chronic hepatocellular toxicity induced massive necrosis of the host/endogenous hepatocytes and a quasi-clonal proliferation of healthy donor hepatocytes transplanted.

The urokinase plasminogen activator (uPa) transgenic mouse, driven by an albumin promoter, was one of the first

**FIG. 47.2.** Regenerative hepatic nodule in the FAH-mutant mouse. Liver cells suspension from a wild-type mouse (FAH<sup>+/+</sup>) was transplanted into a tyrosinemic mouse (FAH<sup>-/-</sup>-mutant mouse). A few weeks after cell transplantation, FAH<sup>+/+</sup> nodules were detected in the diseased liver (Peroxydase-positive hepatocytes stained with anti-FAH antibody). In general, two months after transplantation, most of the tyrosinemic liver is reconstituted by FAH<sup>+/+</sup> hepatocytes.

genetic models (Rhim *et al.*, 1994). In this model, massive engraftment of the donor liver cells was achieved because the transplanted cells had a proliferative growth advantage over the host liver cells and replicated when host cells disappeared. The Fah knockout mouse is another genetic model of hepatocellular toxicity, with the advantage that it reproduces a human lethal inherited liver disease, tyrosinemia type 1, by deleting the fumarylacetoacetate hydrolase (*Fah*) gene (Grompe *et al.*, 1995). The animals develop severe liver disease, which can be rescued by blocking the tyrosine pathway upstream using the drug 2-(2-nitro-4-trifluoromethylbenzyl)-1,3 cyclohexanedione (NTBC). Thus, FAH mutants developed to adulthood can breed and remain healthy until NTBC is removed. After NTBC withdrawal, liver failure occurs, and the mice die within six to eight weeks. When FAH-mutant mice are transplanted intrasplenically with single-cell suspensions of syngeneic hepatocytes from wild-type mice, the FAH-positive cells migrate to the liver, invade the parenchyma, and divide until >95% of the liver cell mass is replaced by donor hepatocytes (see Fig. 47.2) (Overturf *et al.*, 1996). Repopulated animals are healthy, and as few as 100 donor hepatocytes are sufficient to rescue the animal from the lethal liver defect. Moreover, repopulating cells can be serially transplanted to measure their cell division capacity (Overturf *et al.*, 1997).

Because hepatocytes are terminally differentiated cells, which need only limited proliferation to restore liver mass, it was originally thought that hepatocytes have a limited

capacity of proliferation. However, both the urokinase plasminogen activator (uPa) transgenic mouse and the fumarylacetoacetate hydrolase (FAH) knockout mouse demonstrated that hepatocytes have a high proliferative potential. With the uPa transgenic mouse, 12 or more cell divisions were necessary for liver regeneration; in the FAH mouse, Grompe and coworkers serially transplanted the mice with hepatocytes, resulting in an average of 69 divisions. This unique capacity of hepatocytes to regenerate the liver is based on two essential features: extensive and continuous liver injury, and a strong selective advantage for the transplanted cell to survive as compared to the host cells. The preconditioning for hepatocyte engraftment and liver regeneration is similar to what is needed for efficient bone marrow transplantation. Here again, through chemotherapy and/or irradiation, the recipient hematopoietic system is depleted and the donor cells have a strong selective advantage, which allowed engraftment and transplantation of the blood system.

### Transdifferentiation of Hepatocytes into Biliary Cells

Are hepatocytes liver stem cells? Hepatocytes do not fulfill one essential criterion of stem cells, multipotentiality. Hepatocytes may be considered more like what B- and T-cells would be for the immune system. Upon activation, T- or B-cells can self-renew and expand in large numbers to generate plasma cells or activated CD4<sup>+</sup> or CD8<sup>+</sup> T-cells. However, under normal circumstances, T- or B-cells do not generate any myeloid or erythroid cells. Interestingly, hepatocytes have been reported potentially to transdifferentiate into biliary cells, both *in vitro* (Michalopoulos *et al.*, 2002; Nishikawa *et al.*, 2005) and *in vivo* (Michalopoulos *et al.*, 2005). Although no clonal approaches or prospective isolation of hepatocytes had been proposed in these studies, these results, if confirmed, would suggest that hepatocytes can function as facultative stem cells, having both self-renewing capacity as well as possible lineage commitments. As seen in Figs. 47.3 and 47.4 and in the next paragraph, hepatocytes are not a homogeneous population of cells. Consequently, it could still be argued that only a distinct population of primitive hepatocytes may have this “stemness” capacity.

### Hepatocyte Polyploidy and Cell Aging

Hepatocytes are highly differentiated cells of the liver capable of multiple synthetic and metabolic functions. However, hepatocytes can be also viewed as a heterogeneous population of cells containing small and large cells, diploid to polyploidy, mononucleated to binucleated (see Figs. 47.3 and 47.4). The polyploidization of hepatocytes after birth is another interesting physiological process of this specialized cell. During growth and development, hepatocytes undergo dramatic changes, which are characterized by a gradual polyploidization, with the successive appear-

**FIG. 47.3.** Cytospin of mouse adult liver cells. Hepatocytes are a heterogeneous population of cells, small and large, mono- and binucleated. Cells were stained with propidium iodide and counterstained with Hoechst.

ance of tetraploid and octoploid cells with one or two nuclei. In this process, human or rat hepatocytes of a newborn are exclusively diploid ( $2n$ ) but will subsequently generate  $4n$ ,  $8n$ , and eventually  $16n$  mono- and binucleated hepatocytes. The accumulation rate of binucleated and polyploidy cells is very slow in the human, with an intensification of the polyploidization after the age of 50 (Kudryavtsev *et al.*, 1993).

Polyploidy is a general physiological process found in many cellular systems (Anatskaya *et al.*, 1994). Normally, polyploidization is a strategy of cell growth that increases metabolic output and is viewed as an alternative to cell division that is indicative of terminal differentiation and senescence (Sigal *et al.*, 1995, 1999). The cellular mechanism that governs the passage from mononucleated  $2n$  to binucleated  $2 \times 2n$  or mononucleated  $4n$  was recently unveiled and involved the abortion of cytokinesis, which induced the formation of binucleated hepatocytes (Guidotti *et al.*, 2003). In the proposed model, binucleated  $2n$  hepatocytes could divide and generate binuclear tetraploid ( $2 \times 2n$ ) daughter cells. This binucleated ( $2 \times 2n$ ) tetraploid hepatocyte could itself generate two ( $4n$ ) mononucleated cells (see Fig. 47.1). In rodents, studies of the transplanted hepatocytes isolated via flow cytometry using the DNA profile of diploid, tetraploid, and octoploid liver cells showed that all fractions could engraft, proliferate, and regenerate liver tissues (see Fig. 47.4) (Weglarz *et al.*, 2000). These data supported the conclusion that multiple hepatocyte ploidy classes can serve as progenitors for regenerating hepatocyte foci in damaged liver. However, isolation of hepatocytes by centrifugal elutriation into three hepatic fractions—small (16 microns), medium-sized (21 microns), and large (27 microns) hepatocytes—showed that the small fraction had a surprisingly

lower repopulation capacity during the first round of transplantation (Overturf *et al.*, 1999). Clearly, more studies need to be done to understand the self-renewal and commitment potential of these different classes of hepatocytes.

## V. LIVER STEM CELLS

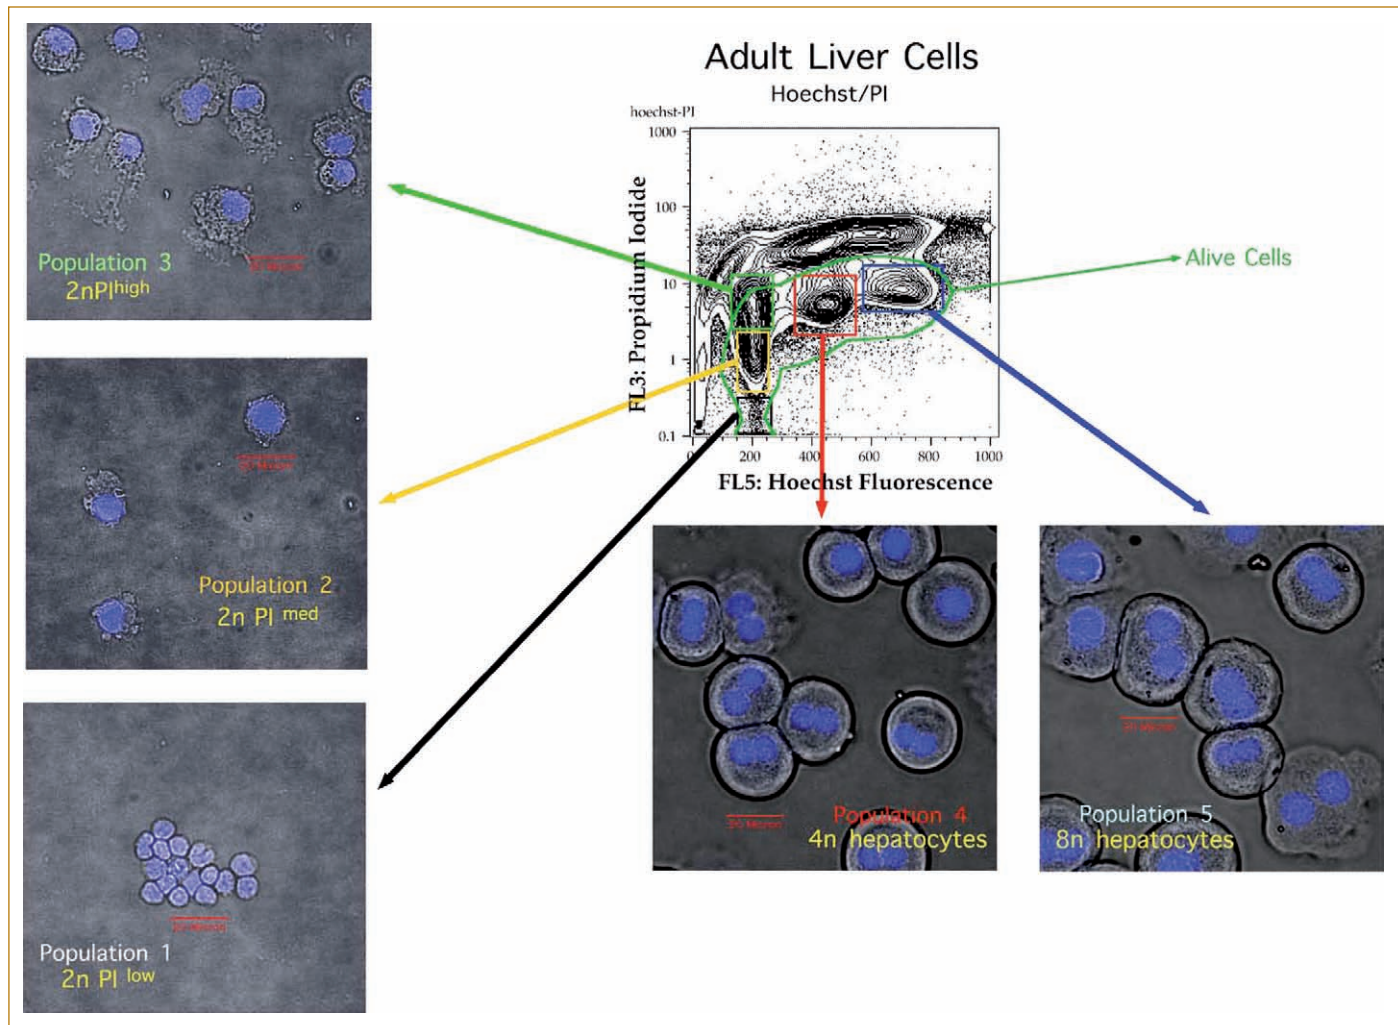

### Liver Development

Mammalian organisms begin as a totipotent stem cell, the fertilized ovum. Then, through a process of specification and determination, cells develop specialized functions and grow into organs. The initiation of liver formation begins from the debut of ventral endoderm from the embryonic foregut. In the mouse, where most of the advances in liver development have been made, hepatic genes are first induced in a segment of definitive endoderm at about 8.5 days of gestation (7–8 somite pair stage, three weeks in the human) (Lemaigre and Zaret, 2004). This induction requires fibroblast growth factor (FGF) from adjacent cardiogenic mesoderm as well as bone morphogenic protein (BMP) from nearby septum transversum mesenchyme. In addition, after hepatic endoderm epithelium becomes more proliferative, interactions with endothelial cells are crucial for this early phase of development. The hepatic diverticulum is divided into cranial and caudal portions. Hepatic cords from the cranial portion invade the septum transversum mesenchyme and develop into the liver parenchyma and intra- and extrahepatic ducts. Gallbladder and cystic duct derive from the caudal portion of the hepatic diverticulum, a region not formed through development in the rat embryo. This would explain why no gallbladder and cystic duct are found in the adult rat (Shiojiri, 1997). Once the liver bud emerges from the developing gut tube, hematopoietic cells migrate in by day 11 in the mouse, and the liver cells are referred to as *hepatoblasts*, which already express liver-specific genes such as albumin (ALB), alpha-fetoprotein (AFP), and cytokeratin 19 (ck19) (see Fig. 47.5) in the human. The hepatoblasts will give rise to definitive hepatocytes and bile duct cells (Fig. 47.1). Recent observations uncovered an unexpected relationship between extrahepatic bile duct morphogenesis and pancreas development, with common factors, like Pdx-1, influencing differentiation of both cell lineages.

### Prospective Identification of Liver Stem/Progenitor Cells

Clonogenic rat cells were the first liver progenitor cells to be prospectively isolated (Kubota and Reid, 2000). Using an *in vitro* colony-forming assay and flow cytometry technology, a population of fetal liver cells, RT1A<sup>1</sup>/OX18<sup>low</sup>/ICAM-1<sup>+</sup>, was isolated at ED13. These cells were considered hepatoblasts and were shown to exhibit bipotential differentiation *in vitro* (hepatocyte and bile duct markers). This finding was followed by the identification of a similar population of hepatoblasts in mouse fetal liver (Tanimizu *et al.*,

**FIG. 47.4.** Isolation of mouse adult liver cells using a fluorescent-activated cell sorter. Liver cells were purified based on their ploidy (DNA staining, Hoechst) and autofluorescence. Diploid cells have low levels of Hoechst and have a low-to-high level of autofluorescence (Populations 1–3). Tetraploid hepatocytes (Population 4) and octoploid hepatocytes (Population 5) have high levels of autofluorescence and are mono- and binucleated cells. Dead cells (propidium iodide-positive cells) were excluded.

2003; Nierhoff *et al.*, 2005). By combining a different culture system with flow cytometry, more primitive fetal liver cells capable of forming large colonies and providing their descendants for a relatively longer period were isolated from mouse fetal livers (Suzuki *et al.*, 2000, 2002). The  $\text{Met}^+/\text{CD49}^{\text{hi/low}}/\text{c-kit}^-/\text{CD45}^-/\text{TER119}^-$  fetal liver cells were clonally propagated in culture and were shown continuously to produce hepatocytes and cholangiocytes while maintaining their primitiveness. When these cells clonally expanded *in vitro* were transplanted into mice, they morphologically and, to some extent, functionally differentiated into hepatocytes and cholangiocytes. Furthermore, these mouse fetal liver cells were capable of differentiating into pancreatic acinar cells and gastric as well as intestinal epithelial cells upon transplantation into these organs. Therefore, these

cells are regarded as endodermal stem cells (Suzuki *et al.*, 2002).

We know very little about the different progenitor populations in human fetal liver. Recently, several isolations and characterizations of human fetal liver stem and/or progenitor cells were described. Using EpCam and magnetic beads (magnetic activated cell sorting, MACS),  $\text{Epcam}^+$  hepatoblasts and hepatic stem cells were isolated from fetal, neonatal, and adult liver and cultured in short- (10 days) and long-term (20 days) assays (Schmelzer *et al.*, 2006).  $\text{EpCAM}^-$  liver cells proved to be more than 95% diploid and polyploid hepatocytes. Hepatic stem cells were  $\text{Epcam}^+$ ,  $\text{NCAM}^+$ ,  $\text{CLDN-3}^+$ ,  $\text{ck19}^+$ ,  $\text{c-kit}^+$ ,  $\text{aquaporin 4}^+$   $\text{Alb}^{\text{low}}$ , and  $\text{AFP}^-$ , while hepatoblasts were  $\text{EpCAM}^+$ ,  $\text{NCAM}^-$ ,  $\text{CLDN-3}^-$ ,  $\text{ck19}^{\text{low}}$ , and  $\text{c-kit}^{\text{low}}$ . No prospective isolation by flow cytom-

**FIG. 47.5.** *In vitro* culture of human fetal liver cells. Human fetal liver cells were cultured for several weeks on stroma. The colony was stained with AFP (alpha-fetoprotein, green), a marker for hepatoblasts, and ck19 (cytokeratin 19, red), a marker for bile duct cells. This colony contains a mix of cells positive for ck19 only (bile duct cells), AFP only (hepatoblasts/small hepatocytes), and ck19/AFP bipotent progenitor cells.

etry, clonal approaches, or *in vivo* transplantation were presented in this work, but more extensive studies from this group are currently under review.

A multipotent progenitor population (hFLMPC) was reported very recently to be capable of differentiating into liver and mesenchymal lineages (Dan *et al.*, 2006). Human fetal liver cells were maintained in culture on feeder layers and the derived colony was clonally isolated by serial dilution. These progenitor cells have the immunophenotype CD34<sup>+</sup>, CD90<sup>+</sup>, c-kit<sup>+</sup>, EPCAM<sup>+</sup>, c-met<sup>+</sup>, SSEA-4<sup>+</sup>, CK18<sup>+</sup>, CK19<sup>+</sup>, Albumin<sup>-</sup>, alpha-fetoprotein<sup>-</sup>, CD44h<sup>+</sup>, and vimentin<sup>+</sup>. Placed in appropriate media, hFLMPC will differentiate into hepatocytes and bile ducts as well as into fat, bone, cartilage, and endothelial cells. Interestingly, hFLMPC survive and differentiate into hepatocytes *in vivo* when transplanted into animal models of liver disease. hFLMPC does not express hepatic markers such as albumin, alpha-fetoprotein, and primitive hepatic transcription factors (HNF1a, HNF3b, and HNF4a) in their undifferentiated state, and it is capable of mesenchymal properties. This result would suggest that hFLMPC is a mesenchymal-epithelial transitional cell, probably derived from a mesendodermal origin. Further analysis and characterization will be necessary to determine the true origin of this human liver progenitor cell.

### Liver Stem Cells and Adult Liver

Hepatocytes and cholangiocytes are the two mature epithelial cells in the adult liver. Both derive from the hepa-

toblast population during embryogenesis of the liver. Unfortunately, very little is known about the identification of an adult liver stem/progenitor cell. There is, however, evidence of the presence of such stem/progenitor cells in adult liver. In rodent injury models, damage to the liver combined with an arrest in the proliferative capacity of hepatocytes leads to proliferation of *oval cells*. These cells are not small hepatocytes but a distinct population of liver cells, which differentiates into hepatocytes and restores the loss of hepatic parenchyma (Fausto and Campbell, 2003; Lowes *et al.*, 2003). A similar population of liver cells, called *ductular hepatocytes*, has been reported in patients suffering a variety of liver diseases (Vessey and de la Hall, 2001). These cells have a gene expression associated with both hepatocytes and cholangiocytes, and their presence has been reported in the histopathology of human diseases, from fulminant hepatitis to primary biliary cirrhosis.

In rodent models, experimental studies have shown that oval cells derive from cells of the biliary epithelium. The precursor of oval cells has been proposed to be the elusive adult liver stem cell and would reside in the canals of Hering. The canals of Hering were originally identified as luminal channels linking the hepatocyte canalicular system to the biliary tree. These channels are in direct physical contact with hepatocytes on the one side and bile duct cells on the other side. Recent studies have described the canals of Hering as the structures that penetrate deep inside the lobules (Saxena and Theise, 2004) and could be considered as a candidate *stem cell niche*. Studies in the rat treated with partial hepatectomy followed by the administration of *N*-2 acetyl-aminofluorene (AAF), a protocol used to generate large populations of oval cells, demonstrated that indeed these cells are located in the canals of Hering before differentiating into hepatocytes (Paku *et al.*, 2004).

### Liver Stem Cells and Cancer

Stem cell biology and cancer biology are inextricably linked. It is widely accepted that cancer from multistep events and stem cells may be the only cells that have a life span that is long enough to acquire the requisite number of genetic changes for neoplastic growth. There is overwhelming evidence that virtually all cancers are clonal; that is, they represent the offspring of a single cell, evolving from a series of sequential mutations due to genetic instability and/or environmental factors. Additionally, transplant experiments have demonstrated that tumor cells are functionally heterogeneous, in that only a limited number of tumor cells are able to initiate tumorigenicity. As the result, cancers can be viewed as newly formed abnormal tissues initiated by a few cancer-initiating cells or cancer stem cells that undergo an aberrant and poorly regulated process of organogenesis. This hierarchy theory for tumor cells in cancer predicts that the tumor would comprise rare cancer-initiating cells that are different from the vast majority of the cells that made

**FIG. 47.6.** Hepatic cell lineage and cancer type. Based on the model of maturation arrest of the liver cell lineage by Stuart Sell (Sell and Ilic, 1997). The diversity of liver cancers is based on cancer-initiating cells, which have acquired self-renewing capacity at a different stage of differentiation in the hepatic pathway. Each cancer-initiating cell can be regarded as a cancer stem cell, capable of both self-renewal and to some extent differentiation. A major challenge will be the isolation of the cancer-initiating cells in each tumor type.

the tumor and would have a function analogous to that of normal stem cells. A hallmark of all cancers is the capacity for unlimited self-renewal, which is also a defining characteristic of normal stem cells, as described earlier. Given these shared attributes between cancer-initiating cells and stem cells, it has been proposed that cancers may be initiated by transforming events that take place in normal stem cells, which would give rise to a cancer stem cell. Alternatively, cancer cells may acquire signaling pathways associated with stem cells functions (see, for review, Reya *et al.*, 2001).

An in-depth review of liver cancer etiology is beyond the scope of this section. Here we focus only on the possible role of stem cells and progenitor cells as the cellular origin for human liver cancers (see Fig. 47.6). During liver development, hepatoblastomas are the most common liver tumors in childhood. In these pediatric liver tumors, cells resembling progenitor cells have been observed. It has been postulated that hepatoblastomas have a stem cell origin, for they can be composed of both epithelial and mesenchymal tissue components, with possible intrahepatic bile duct-like formations or mixed type (teratoid hepatoblastoma). The presence of different cell populations bearing stem cell markers in human hepatoblastoma have been observed, with ductal cells coexpressing stem cell markers and hepatic lineage markers phenotypically resembling hepatic stem-like cells. These findings support the thesis that stem cells play a role in the histogenesis of hepatoblastoma (Fiegel *et al.*, 2004). An interesting parallel could be made between the recent isolation of a fetal mesenchymal–epithelial tran-

sitional cell, described earlier, and the tumor cells of origin in hepatoblastomas (Dan *et al.*, 2006). However, no conclusive information on the cellular origin of hepatoblastomas has been reported.

For adult liver, most of the chronic human liver diseases are characterized by progenitor cell activation, the ductular reaction, which comprises expansion of a transit-amplifying cell compartment of small “biliary” cells. These cells can differentiate into biliary and hepatic lineages. The ductular reaction is the human equivalent of rodent oval cell activation, a cellular response to carcinogenic agent inhibiting the proliferation of mature hepatocytes after a regenerative stimulus. Cirrhotic stages of a variety of chronic liver diseases are characterized by hepatocyte senescence, which should trigger similar progenitor activation. The degree of progenitor cell activation increases with the severity of the disease, making such cells very likely carcinogen targets.

However, in the adult liver the identity of the cancer-initiating cell is more problematic for the two major primary tumors, hepatocellular carcinoma (HCC), one of the most common cancers worldwide and the major consequence of chronic viral hepatitis, and cholangiocarcinoma (CC). Both cancers evolve from focal precursor lesions that reflect the accumulation of genetic and epigenetic alterations, contributing to multistep carcinogenesis. In HCC, small dysplastic foci reflecting the earliest premalignant lesions consist of progenitor cells and intermediate hepatocytes. HCCs express markers of progenitors and biliary cells such as ck19, ck7, and OV6, and ck19 expression has been associ-

ated with a worse prognosis after surgical treatment (Roskams, 2006). This observation is a very strong argument in favor of the progenitor cell origin of at least part of the HCCs. It also seems likely that mature polyploid hepatocytes are not the cells of origin of HCCs, a cancer of diploid cells in precursor lesions. Based on animal models of experimental hepatocarcinogenesis, four distinct cell lineages susceptible of neoplastic transformation have been anticipated (Sell, 2002). This hypothesis is based on the fact that there is a considerably different cellular response to injuries in the many different models of hepatocarcinogenesis. Out of the four cell lineages, hepatocytes would be implicated in the initiation of some models of HCC, while biliary epithelium cells would be the cell responsible in some other models of CC. Hepatic progenitor cell and oval cell activations would be responsible for initiating many liver cancers. Finally, periductular cells that respond to periportal injury would also be involved as the last candidate tumor cells (Sell, 2002).

## VI. LIVER STEM CELLS AND THERAPEUTIC APPROACHES

### Stem Cell Therapy for Liver Diseases

#### An Urgent Need for Alternative Approaches to Orthotopic Liver Transplantation (OLT)

Liver diseases, such as infections, alcohol-related ailments, cancers, and autoimmune, metabolic, and drug-induced liver diseases represent a major health burden in modern times. Chronic hepatitis, currently the most common cause for orthotopic liver transplantation (OLT), afflicts an estimated 4 million people in the United States alone (350 million people worldwide), and acute liver failure is, in general, associated with unacceptable high mortality rates of up to 90%. Most of these conditions lead to acute or chronic liver failure if no definitive treatment can be offered. The only available routine treatment for hepatic failure is allogeneic, OLT, a procedure that cures some of these end-stage chronic liver diseases. But the procedure is costly and requires the use of lifelong immunosuppressive drugs. Plus, the availability of donor livers is limited to less than 5000 annually (United States alone). Patients on the waiting list for OLT, using fairly stringent criteria of acceptance, are severalfold greater, and the demand for liver transplantation is on the increase while the limited supply of organs for transplantation has not increased. With organ transplantation not available for a large fraction of patients with liver disease to liver failure, cell transplantation for the treatment of acute and chronic liver diseases is an increasingly attractive prospect. Lastly, treating conditions such as metabolic diseases, where overall liver functions generally are intact, with a surgical procedure like OLT is certainly quite extreme and should indeed be substituted by a less radical, less expensive, and potentially long-term curable procedure like cell therapy.

#### Clinical State of the Art of Hepatocyte Transplantation in Patients with Inborn Errors of Metabolism

Due to the successes of hepatocyte transplantation in animals, several groups have been evaluating cell therapy in a variety of human diseases (see review by Gupta and Chowdhury, 2002; Selden and Hodgson, 2004). Several dozen of patients have undergone isolated hepatocyte transplantation for metabolic diseases. Cell-based transplantations have been applied in individual cases and in small, uncontrolled series of patients suffering from inborn errors of metabolism, mainly involving the liver (summarized by Burlina, 2004). Although the beneficial outcome in some of these liver cell transplantations has been very encouraging (Fox *et al.*, 1998; Strom *et al.*, 1999), the limited clinical experience in hepatocyte transplantation is a current problem. *Importantly, the single most outstanding issue preventing the use of hepatocyte transplantation is the limited availability of hepatocytes.* The normal source of cells for hepatocyte transplantation is donor livers. Because hepatocyte transplantation is still experimental and, for ethical reasons, as many patients are dying and will still die waiting for a liver transplant, transplanted liver cells are obtained from organs unsuitable for transplantation. While a liver that has suffered extensive trauma and is unsuitable for transplantation can still be used for isolation of a few billion healthy hepatocytes, it nonetheless has a high risk of providing cells of poor quality and viability. The problem of cell availability would be solved by alternative sources of hepatocytes. The use of stem and progenitor cells, liver derived, to be applied in the treatment of inherited and acquired liver diseases could solve the problem of hepatocyte availability. In addition, the search for alternatives to liver cells (not liver derived) could also produce an adequate source of cells. The possibility of deriving mature liver cells from ES cells and other stem cells has elicited considerable interest. We need to extend our current knowledge and understanding of these various stem cell populations to make possible their future therapeutic uses in cell transplantation, liver regeneration, and bioartificial liver devices.

### Stem Cells and Anticancer Therapy

Because of the importance stem cells and progenitor cells may have in cancer, understanding what controls the maintenance of stem cells (self-renewal) and the differentiation signals (cell commitment) will give insights into the cellular mechanism involved in cancer (see review by Sell, 2006). One such signal that is important at the stem cell level for maintaining proliferation at an early stage of differentiation and that may have a similar role in cancer is the Wnt/ $\beta$ -catenin pathway. Wnt was discovered as a putative proto-oncogene before it was recognized as a homolog of the *Drosophila* wingless (wnt-1) gene, a member of a family of genes highly conserved that secreted signaling molecules

regulating cell-to-cell interaction during wing embryogenesis of the fly. The Wnt pathway has been also associated with colon cancer and the familial adenomatous polyposis, an identified genetic predisposition for colon cancer. Here the adenomatous polyposis coli (APC) gene codes for a tumor-suppressor protein, which binds to  $\beta$ -catenin and down-regulates its function. The APC gene is a major suppressor gene in colon cancer, and molecular lesions of the gene inhibit the phosphorylation and degradation of  $\beta$ -catenin. As a consequence,  $\beta$ -catenin concentration increases, resulting in colon cell proliferation and cancer. Mutations and overexpression of  $\beta$ -catenin is found in most human liver cancer, such as HCC and hepatoblastomas, and is postulated to be driving the proliferation of cancer cells. Treatment of liver cancers targeting  $\beta$ -catenin is one novel approach for therapeutic intervention. More cell signaling pathways, including Notch, BPM, and sonic hedgehog, may ultimately lead to new drugs for anticancer treatments (Sell, 2002).

## VII. CONCLUSION

Major progress has been made in the identification of liver stem and progenitor cells. However, more needs to be done. So far only a few laboratories have prospectively isolated fetal liver cells, but there is no clear consensus about the phenotype of fetal liver stem cells. For adult liver, the liver stem cells are still elusive.

A cell-based therapy with the transplantation of hepatocytes in small-animal models has demonstrated their efficacy, and clinical trials for human liver diseases may be achieved within the near future. But much remains to be learned. We still need to determine the best “engrafting cell” for cell transplantation: adult hepatocytes, fetal hepatocytes, or liver stem cells. Cell expansion will also be an issue for a viable therapeutic procedure. Finally, transplanted cells must have a selective advantage to engraft and repopulate the diseased liver. A starting point will be genetic metabolic disorders, which could provide the environment necessary for an efficient and therapeutic cell transplantation. But the prospects for the future of liver diseases, in general, will be a procedure similar to myeloablation, necessary to prepare the patient for bone marrow or hematopoietic stem cell engraftment.

For liver cancers, identification of cancer-initiating cells is in its infancy. As with normal stem and progenitor cells, cancer stem and progenitor cells will need to be prospectively identified. The study of the tumor cell hierarchy in liver cancer may help our understanding of the normal cell hierarchy in adult liver. Finally, the clinical application of the stem cell theory of cancer lies in the development of novel therapies to induce terminal differentiation of cancer cells. Of course, an understanding of the cellular mechanisms that control stem cell self-renewal and differentiation is key in the development of new approaches for both cancer- and cell-based therapies.

### I. INTRODUCTION

Cell-based therapies for liver failure offer the potential to augment or replace whole-organ transplantation. However, the development of such therapies poses unique challenges, stemming largely from the complexity of liver structure and function. The field of liver-tissue engineering encompasses several approaches collectively aimed at providing novel therapeutic options for liver disease patients as well as elucidating fundamental characteristics of liver biology. These approaches include the development of (1) *in vitro* model systems that recapitulate normal liver function, (2) extracorporeal bioartificial liver devices for the temporary support of liver failure patients, and (3) three-dimensional implantable therapeutic constructs. Advances in each of these aspects are reviewed in this chapter, within the context of current treatments for liver disease and additional clinical alternatives, such as surgical advancements for organ transplant and cell transplantation strategies. Critical issues relevant to all of these areas, including cell sourcing and animal models, are also discussed.

### II. LIVER FAILURE AND CURRENT TREATMENTS

Liver failure is a significant health problem, representing the cause of death of over 40,000 individuals in the United States every year, and it can generally be separated into two major categories: fulminant hepatic failure, also referred to as *acute liver failure*, and chronic hepatic failure resulting from chronic end-stage liver disorders. The term *fulminant hepatic failure* is utilized for cases in which hepatic encephalopathy develops within two weeks of the initial onset of jaundice, whereas *subfulminant hepatic failure* is applied to cases in which encephalopathy develops between two weeks and three months after the appearance of initial symptoms. Hepatic encephalopathy is a neuropsychiatric condition that can be divided into four stages, ranging from minor effects, such as mild confusion and sleep disorder, to deep coma. Although fulminant hepatic failure is relatively rare, with approximately 2000 cases in the United States per year, it exhibits a high mor-

tality rate, approximately 28% (W. M. Lee, 2003). The major identified causes of fulminant hepatic failure include acetaminophen overdose, idiosyncratic drug reactions, and viral hepatitis A and B (W. M. Lee, 2003). Of note, a 2002 multicenter etiology study illustrated that 17% of fulminant hepatic failure cases remained of indeterminant origin (Ostapowicz *et al.*, 2002). In addition to hepatic encephalopathy, other clinical aspects of fulminant hepatic failure are infection, both bacterial and fungal, coagulopathy, as well as broad-spectrum metabolic, cardiorespiratory, and hemodynamic abnormalities. Though spontaneous recovery has been observed due to the regenerative capacity of the liver, this type of recovery is difficult to predict, and it rarely occurs in such etiologies as idiosyncratic drug toxicity and hepatitis B (W. M. Lee, 2003). Liver transplantation is the only therapy shown to alter mortality directly, and therefore it is the standard of care in most clinical settings. As a result, all fulminant hepatic failure patients who meet the criteria for orthotopic liver transplant are immediately listed as United Network for Organ Sharing Status 1 on presentation. Factors that preclude this designation are irreversible brain damage, unresponsive cerebral edema, extrahepatic uncontrollable sepsis and malignancy, and multisystem organ failure. Despite the effectiveness of liver transplant in improving short-term survival of fulminant hepatic failure patients, the utility of this approach remains limited, due to the scarcity of donor organs.

Liver failure due to chronic liver diseases, while exhibiting a longer time course of disease pathogenesis, is much more common than fulminant failure, with chronic liver disease and cirrhosis representing the 12th leading cause of death (1.1% of total deaths) in the United States in 2002 (Kochanek *et al.*, 2004). The most common causes of chronic liver disease are hepatitis C, alcohol-induced and nonalcoholic fatty liver disease (NAFLD), and hepatitis B (W. R. Kim *et al.*, 2002). Other etiologies include primary sclerosing cholangitis, primary biliary cirrhosis,  $\alpha_1$ -antitrypsin deficiency, autoimmune hepatitis, hereditary hemochromatosis, and liver cancer. The prevalence of hepatitis C infection in the United States population has been estimated at 1.8%, or nearly 4 million individuals (Alter *et al.*, 1999). Notably, cirrhosis initiated by hepatitis C infection is the most frequent cause for liver transplantation, accounting for 40–50% of individuals who have undergone transplant and those on the waiting list (R. S. Brown, 2005). In addition, the long-term inflammation precipitated by chronic hepatitis C infection can also promote the development of hepatocellular carcinoma. As a result, substantial efforts are focused on understanding hepatitis C viral pathogenesis and the development of approaches for the improved control of the virus before and after transplantation. Taken together, so-called fatty liver diseases also comprise a major proportion of chronic liver disease patients (W. R. Kim *et al.*, 2002). In particular, NAFLD is an increasingly prevalent condition in the United States, present in approximately 20% of adults,

of which a subset (2–3% of adults) exhibits nonalcoholic steatohepatitis (NASH), defined by the presence of characteristic injury and necroinflammatory changes in addition to excessive fat accumulation. NAFLD pathogenesis has been shown to be associated with risk factors and conditions such as obesity, type 2 diabetes mellitus, hyperlipidemia, hyperinsulinemia, and insulin resistance. Collectively, chronic liver disorders can progress toward the eventual development of dangerous conditions, including portal hypertension and hepatic encephalopathy. This progression, often referred to as *acute on chronic liver failure*, is analogous to fulminant hepatic failure cases; organ transplantation is the only effective therapy currently. As a means to determine organ allocation more accurately to patients on the liver transplant waiting list, the MELD (mathematical model for end-stage liver disease) system was implemented in 2002, which assigns a priority score based on three prognostic indicators: bilirubin level, creatine level, and INR, a measure of blood-clotting time (R. S. Brown, 2005). Although overall improvements in liver allocation have been achieved following the introduction of the MELD system, regional variations in MELD scores exist, and the ability of this model to accurately predict outcomes across the entire score distribution and for distinct pathologies is less clear.

In order to expand the supply of available livers, several surgical options have been pursued, including the use of non-heart-beating donors and split liver transplants from cadaveric or living donors (K. A. Brown, 2005). Partial liver transplants take advantage of the body's role in the regulation of liver mass and the significant capacity for regeneration exhibited by the mammalian liver. This regenerative process has been extensively examined utilizing experiments in rodent models, which demonstrate that partial hepatectomy or chemical injury induces the proliferation of the existing mature cell populations within the liver, including hepatocytes, bile duct epithelial cells, and others, resulting in the replacement of lost liver mass. However, liver regeneration is difficult to control clinically; and although partial liver transplants have demonstrated some effectiveness, biliary and vascular complications are major concerns in these procedures (K. A. Brown, 2005). Furthermore, in spite of these surgical advances and improvements in organ allocation, there is an increasing divergence between the number of patients awaiting transplantation and the number of available organs, suggesting that it is unlikely that liver transplantation procedures alone will meet the increasing demand.

Consequently, alternative approaches are needed and are being actively pursued, including several nonbiological extracorporeal support systems (discussed in more detail later in this chapter), such as plasma exchange, plasmapheresis, hemodialysis, and hemoperfusion over charcoal or various resins. These systems have shown limited success, likely due to the narrow range of functions inherent to these devices. The liver exhibits a complex array of over 500 functions, including detoxification, synthetic, and metabolic

processes. Hence, recapitulation of a substantial number of liver functions will be required to offer sufficient liver support. As a means to provide the multitude of known as well as currently unidentified liver functions, cell-based therapies have been proposed as an alternative to both organ transplantation and the use of strictly nonbiological systems (Allen and Bhatia, 2002). These therapies encompass approaches aimed at providing temporary support, such as extracorporeal bioartificial liver (BAL) devices, as well as more permanent adjunct interventions, such as cell transplantation, transgenic xenografts, and implantable hepatocellular constructs (Fig. 48.1). Collectively, the development of these types of cell-based therapies for liver disease is a major aim of liver-tissue engineering, and the fundamental advances and current status of these approaches are reviewed in this chapter.

### III. CELL SOURCES FOR LIVER CELL-BASED THERAPIES

The choice of cell type is a critical parameter for any cell-based therapy. Table 48.1 highlights some of the key issues regarding the use of various cell sources. Immortalized hepatocyte cell lines, such as HepG2 (human hepatoblastoma) (Kelly and Darlington, 1989), the HepG2-derived line C3A (Ellis *et al.*, 1996), HepLiu (SV40 immortalized) (J. Liu *et al.*, 1999), and immortalized fetal human hepatocytes (Yoon *et al.*, 1999), have been utilized as readily available surrogates for hepatic tissue. However, it has been suggested that these cells lack the full functional capacity of primary adult hepatocytes, and for clinical applications there is a risk that oncogenic factors could be transmitted to the patient. Thus, the generation of conditionally immortalized lines and the incorporation of inducible suicide genes have been considered as potential precautionary measures. The use of primary hepatocyte-based systems could potentially eliminate these issues and provide the appropriate collection of liver functions. Primary porcine hepatocytes have been utilized in a range of BAL device configurations, with some encouraging results. However, the utility of xenogeneic

porcine cells for human liver therapies is restricted by immunogenicity and the potential for xenozoonotic transmission of infectious agents such as porcine endogenous retrovirus (PERV).

Primary human hepatocytes are ultimately the preferred cell type for cell-based therapies, and the development of primary hepatocyte-based approaches is the focus of substantial ongoing research. Yet progress has been hindered by the limited supply of primary human hepatocytes and certain aspects of hepatocyte physiology. Discussed in

**FIG. 48.1.** Cell-based therapies for liver disease. Extracorporeal devices perfuse the patient's blood or plasma through bioreactors containing hepatocytes. Hepatocytes are transplanted directly or implanted on scaffolds. Transgenic animals are being raised in order to reduce complement-mediated damage of the endothelium. From Allen *et al.* (2001).

**Table 48.1.** Cell sources for liver therapies

#### Cell source

##### Primary hepatocytes

Human, xenogeneic

##### Immortalized hepatocyte lines

Tumor-derived, SV40, telomerase, spontaneously immortalized

##### Stem cells

Embryonic, liver progenitors (hepatoblasts, oval cells), other lineages (HSC, MAPC)

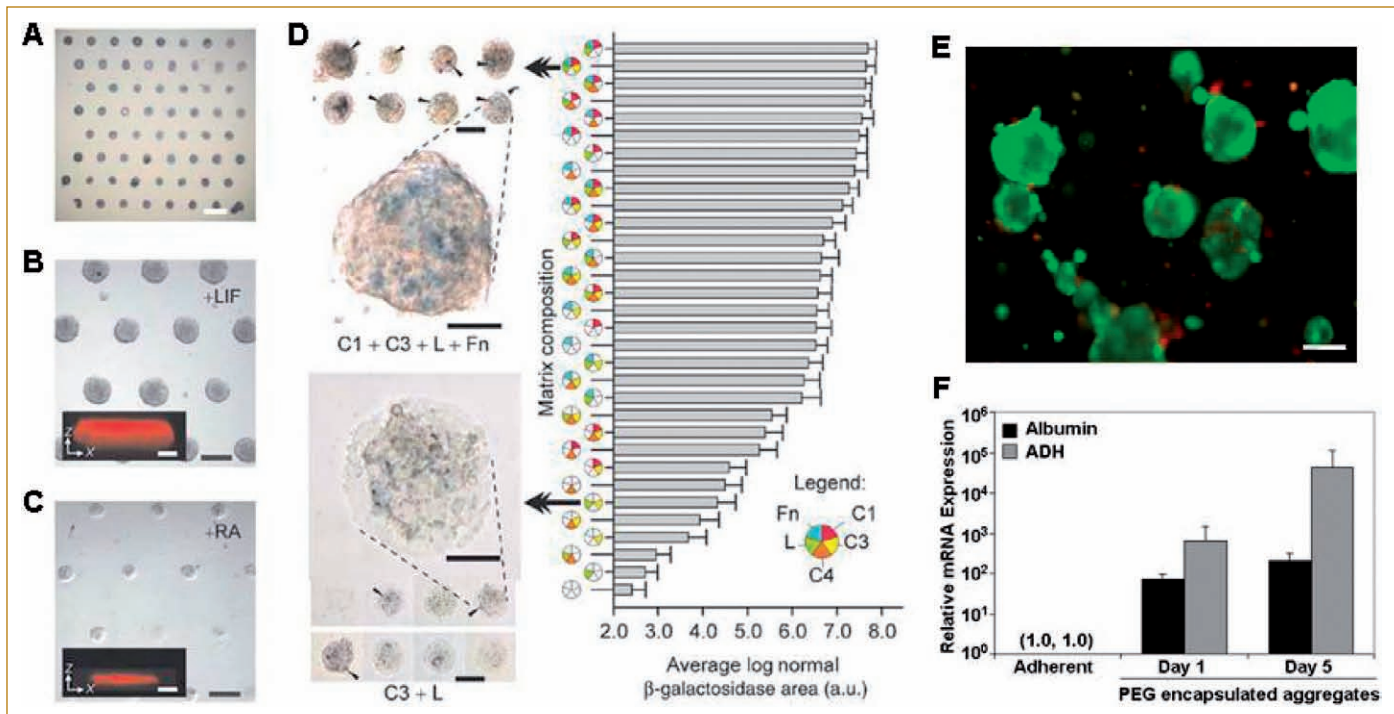

#### Critical issues

Sourcing, expansion, phenotypic instability, immunogenicity, safety (xenozoonotic)

Range of functions, genomic instability, safety (tumorigenicity)

Sourcing, differentiation efficiency, phenotypic instability, immunogenicity, safety (tumorigenicity)

**Abbreviations:** SV40, simian virus 40; HSC, hematopoietic stem cells; MAPC, multipotent adult progenitor cells.

**FIG. 48.2.** Platforms for studying hepatocyte differentiation of embryonic stem cells and liver progenitors. (A) Bright-field alkaline phosphatase staining of day 1 ES cultures on ECM microarrays in 15% serum medium (scale bar, 1 mm). (B, C) Phase-contrast images of day 3 arrays cultured with LIF (B) and with RA (C). Cells cultured with LIF showed three-dimensional features (in B, inset x-z confocal section, ~77-μm thickness). In contrast, RA-induced cells grew as a relatively thin sheet (in C, inset x-z section, ~25-μm thickness). Scale bars, 250 μm (inset scale bars, 50 μm). (D) Bright-field micrograph of selected X-gal-stained ECM microarray conditions after 3 d of culture in RA. C1 + C3 + L + Fn (top left images) induced higher *Ankrd17* reporter activity (arrowheads) than was seen in cells cultured on C3 + L (bottom left images). Scale bars, 250 μm. Magnified views of reporter activity: scale bars, 50 μm. Bar graph: hierarchical depiction of “blue” image area (pooled data from four microarrays) for each of the matrix mixtures. Error bars, s.e.m. ( $n = 32$ ). The C1 + C3 + L + Fn culture condition induced ~27-fold more β-galactosidase image area than the C3 + L cultures (Flaim *et al.*, 2005). (E) BMEL cell aggregates encapsulated within PEG hydrogels exhibit high viability. Fluorescent labeling distinguished viable (green) from nonviable (red) cells. Scale bar, 100 μm. (F) Expression of albumin (black bars) and alcohol dehydrogenase (ADH, grey bars) mRNA was determined by real-time quantitative RT-PCR at day 1 and day 5 following encapsulation of aggregated BMEL cells. Expression for each gene is displayed relative to basal expression exhibited by adherent BMEL cells prior to aggregation. The housekeeping gene, HPRT, was utilized as a normalization control, and data are presented as the mean ± SD ( $n = 3$ , independent experiments).

more detail later, hepatocytes exhibit a loss of liver-specific functions under many conditions *in vitro*. In addition, particularly for human hepatocytes, despite the significant proliferative capacity during regenerative responses *in vivo*, mature hepatocyte proliferation in culture is limited (Mitaka, 1998). As a result, alternative cell sources for liver cell-based therapies are being investigated, such as diverse stem cell populations, which can retain significant proliferative ability *in vitro* and exhibit either pluripotency or multipotency, thereby constituting a possible source of hepatocytes as well as other liver cell types. Preliminary evidence suggests that pluripotent embryonic stem cells can be induced to differentiate toward the hepatocyte lineage in culture (Chinzei *et al.*, 2002; Hamazaki *et al.*, 2001; Ishizaka *et al.*, 2002; Yamada *et al.*, 2002), and methods to improve the range of acquired hepatocyte functions as well as differentiation efficiency continue to be explored (Heng *et al.*, 2005). Recently, an extracellular matrix microarray platform was utilized to

examine the influence of combinatorial mixtures of matrix molecules on embryonic stem cell differentiation toward an early hepatic fate (Fig. 48.2) (Flaim *et al.*, 2005). In this system, an approximately 140-fold difference in the induction of an early hepatic marker (*Ankrd17*) was observed between the least and the most efficient conditions (Fig. 48.2), underscoring the importance of high-throughput technologies in the elucidation of factors affecting stem cell differentiation.

In addition to embryonic stem cells, various fetal or adult stem/progenitor populations have similarly been investigated. For example, multipotent adult progenitor cells (MAPC) derived from bone marrow have been shown to exhibit hepatocyte differentiation potential (Schwartz *et al.*, 2002). Fetal hepatoblasts and oval cells are also intriguing possible cell types for liver cell-based therapies. Hepatic development proceeds through the differentiation of liver precursor cells, termed *hepatoblasts*, which exhibit bipoten-

tial differentiation capacity, defined by the ability to differentiate into both hepatocytes and bile duct epithelial cells (cholangiocytes) (Lemaigre and Zaret, 2004). Notably, in certain types of severe and chronic liver injury, an adult progenitor cell population, termed *oval cells*, which shares many phenotypic markers and functional properties with fetal hepatoblasts, mediates compensatory liver repair through a similar differentiation program (Sell, 2001). Exposure to toxins or carcinogens that block hepatocyte proliferation, and consequently normal liver regeneration, results in the proliferation of oval cells within the liver and subsequent liver repair due to the differentiation of these cells. Recent work by Weiss and colleagues demonstrates the development of bipotential mouse embryonic liver (BMEL) cell lines that are derived from mouse E14 embryos and exhibit characteristics reminiscent of fetal hepatoblasts and oval cells (Strick-Marchand and Weiss, 2002). In particular, these cell lines are nontransformed and proliferative, demonstrate up-regulation of hepatocyte or bile duct epithelial markers under distinct culture conditions *in vitro* (Strick-Marchand and Weiss, 2002), and exhibit the capacity to home to the liver and undergo bipotential differentiation *in vivo* within a regeneration context (Strick-Marchand *et al.*, 2004). This system highlights the potential of progenitor cell lines for tissue repair. As such, toward the eventual incorporation of BMEL cells into implantable tissue-engineered constructs, and discussed in more detail later in this chapter, BMEL cells have been successfully encapsulated within a biomaterial scaffold (PEG hydrogel), and their differentiation toward the hepatocyte lineage was demonstrated to proceed efficiently in this system (Fig. 48.2).

Although diverse stem and progenitor cell populations exhibit vast potential regarding integration into hepatic therapies, many challenges remain, including the ability to dictate and enhance differentiation, particularly within multicellular systems. Furthermore, regardless of the cell source, the stabilization of hepatocyte functions remains a primary issue. Microenvironmental signals, including soluble mediators, cell–extracellular matrix interactions, and cell–cell interactions, have been implicated in the regulation of hepatocyte function. Accordingly, the development of robust hepatocyte *in vitro* culture models that allow for the controlled reconstitution of these environmental factors is a fundamental prerequisite toward a thorough understanding of mechanisms regulating hepatocyte processes and the improved functionality of liver cell-based therapies.

#### IV. *IN VITRO* HEPATIC CULTURE MODELS

An extensive range of liver model systems have been developed, some of which include: perfused whole-organs and wedge biopsies; precision-cut liver slices; isolated primary hepatocytes in suspension or cultured on extracellular matrix; immortalized liver cell lines; isolated organelles, membranes, or enzymes; and recombinant systems expressing specific drug metabolism enzymes (Guillouzo,

1998). While perfused whole organs, wedge biopsies, and liver slices maintain many aspects of the normal *in vivo* microenvironment and architecture, they typically suffer from short-term viability (<24 h) and limited nutrient/oxygen diffusion to inner cell layers. Purified liver fractions and single-enzyme systems are routinely used in high-throughput systems to identify enzymes involved in the metabolism of new pharmaceutical compounds, although they lack the complete spectrum of gene expression and cellular machinery required for liver-specific functions. In addition, cell lines derived from hepatoblastomas or from immortalization of primary hepatocytes are finding limited use as reproducible, inexpensive models of hepatic tissue. However, such lines are plagued by abnormal levels and a repertoire of hepatic functions (Sivaraman *et al.*, 2005), perhaps most notably the divergence of nuclear receptor-mediated regulation of cytochrome P450 enzymes (Kawamoto *et al.*, 1999). Though each of these models has found utility for focused questions in drug metabolism research, isolated primary hepatocytes are generally considered to be most suitable for constructing *in vitro* platforms for a multitude of applications. A major limitation in the use of primary hepatocytes is that they are notoriously difficult to maintain in culture, due to the precipitous decline in viability and liver-specific functions on isolation from the liver (Guillouzo, 1998). Accordingly, substantial research has been conducted since the mid-1980s toward elucidating the specific molecular stimuli that can maintain phenotypic functions in hepatocytes. In subsequent sections, we present examples of strategies that have been employed to improve the survival and liver-specific functions of primary hepatocytes in culture.

#### *In Vivo* Microenvironment of the Liver

In order to engineer an optimal microenvironment for hepatocytes *in vitro*, one can utilize as a guide the precisely defined architecture of the liver, in which hepatocytes interact with diverse extracellular matrix molecules, nonparenchymal cells, and soluble factors (i.e., hormones, oxygen) (Fig. 48.3). Structurally, the two lobes of the liver contain repeating functional units called *lobules*, which are centered on a draining central vein. Portal triads at each corner of a lobule contain portal venules, arterioles, and bile ductules. The blood supply to the liver comes from two major blood vessels on its right lobe: the hepatic artery (one-third of the blood) and the portal vein (two-thirds). The intrahepatic circulation consists of sinusoids, which are small, tortuous vessels lined by a fenestrated basement membrane lacking endothelium that is separated from the hepatocyte compartment by a thin extracellular matrix region termed the *space of Disse*. The hepatocytes, constituting ~70% of the liver mass, are arranged in unicellular plates along the sinusoid, where they experience homotypic cell interactions. Several types of junctions (i.e., gap junctions, cadherins, and tight junctions) and bile canaliculi at the interface of

**FIG. 48.3.** The precisely defined architecture of the repeating unit of the liver, the lobule. Hepatocytes are arranged in cords along the length of the sinusoid, where they interact with extracellular matrix molecules, nonparenchymal cells, and gradients of soluble factors. Nutrient- and oxygen-rich blood from the intestine flows into the sinusoid via the portal vein. After being processed by the hepatocytes, the blood enters the central vein and into the systemic circulation. Reproduced with permission from J. Daugherty.

hepatocytes facilitate the coordinated excretion of bile to the bile duct and subsequently to the gall bladder. Nonparenchymal cells, including stellate cells, cholangiocytes (biliary ductal cells), sinusoidal endothelial cells, and Kupffer cells (macrophages), interact with hepatocytes to modulate their diverse functions. In the space of Disse, hepatocytes are sandwiched between layers of extracellular matrix (collagen types I–IV, laminin, fibronectin, heparin sulfate proteoglycans), the composition of which varies from the portal triad to the central vein (Reid *et al.*, 1992).

Within the liver lobule, hepatocytes are partitioned into three zones, based on morphological and functional variations along the length of the sinusoid (zonation). Zonal differences have been observed in virtually all hepatocyte functions. For instance, compartmentalization of gene expression is thought to underlie the capacity of the liver to operate as a “glucostat.” Furthermore, zonal differences in expression of cytochrome-P450 enzymes have also been implicated in the zonal hepatotoxicity observed with some xenobiotics (Lindros, 1997). Possible modulators of zonation include blood-borne hormones, oxygen tension, pH levels, extracellular matrix composition, and innervation. Therefore, a precisely defined microarchitecture, coupled with specific cell–cell, cell–soluble factor, and cell–matrix interactions allows the liver to carry out its many diverse functions, which can be broadly categorized as protein

synthesis (i.e., albumin, clotting factors), cholesterol metabolism, bile production, glucose and fatty acid metabolism, and detoxification of endogenous (i.e., bilirubin, ammonia) and exogenous (drugs and environmental compounds) substances.

## Two-Dimensional Cultures

Numerous studies have illustrated improvements in the maintenance of primary hepatocyte morphology, survival, and liver-specific functions through modifications in culture conditions. For instance, supplementation of culture medium with low concentrations of hormones, corticosteroids, growth factors, vitamins, amino acids, or trace elements can stabilize the hepatic phenotype (Guillouzo, 1998). In addition, nonphysiologic factors, such as Phenobarbital (drug inducer) and dimethylsulfoxide (organic solvent), are also effective (Isom *et al.*, 1985; Miyazaki *et al.*, 1985). Some complex serum-free hormonally defined media preparations have also been proposed for culturing hepatocytes; however, these formulations often do not maintain liver-specific gene expression and differentiated functions beyond a few days (Guillouzo, 1998). A few mitogenic and comitogenic factors can induce proliferation in hepatocytes under standard culture conditions. For example, when plated at low densities and maintained in serum-free culture medium supplemented with nicotinamide and epidermal growth factor, about 15% of rat hepatocytes undergo three rounds of cell divisions (Mitaka *et al.*, 1991). Human hepatocytes have also displayed proliferation when stimulated with epidermal growth hormone, hepatocyte growth hormone, or human serum (Blanc *et al.*, 1992). However, such limited growth is unlikely to meet the demand for the several billion hepatocytes required for cell-based therapies.

The impact of extracellular matrix on the differentiated functions of hepatocytes has been widely studied. In general, the efficiency of hepatocyte attachment is enhanced by coating substrates with simple extracellular matrix proteins (typically collagen); however, in most cases a concomitant increase in hepatocyte spreading leads to a loss of liver-specific functions (LeCluyse *et al.*, 1996). Presentation of extracellular matrices of different compositions and topologies can stabilize hepatocyte morphology and a limited set of phenotypic functions. For instance, hepatocyte culture on biomatrix, a complex mixture of extracellular matrix components extracted from liver, has been shown to improve hepatocyte function as compared to monolayers on collagen (LeCluyse *et al.*, 1996; Lin *et al.*, 2004). In order to systematically probe the role of distinct extracellular matrix molecules, the matrix microarray platform for embryonic stem cells described earlier was also utilized for primary hepatocyte culture. These experiments similarly revealed a synergistic influence of extracellular matrix combinations on hepatocyte function (Flaim *et al.*, 2005). Furthermore, when sandwiched between two layers of gelled collagen, hepatocytes from a variety of species maintain a cuboidal

shape, secrete albumin, and synthesize urea (marker of nitrogen metabolism) (Guillouzo, 1998). Rat hepatocytes, in particular, secrete albumin at a high rate for 40 days in sandwich cultures, exhibit improved cytochrome P450 induction, and form a contiguous, anastomosing network of bile canaliculi indicative of polarity (Dunn *et al.*, 1989; LeCluyse *et al.*, 1994). Even though two-dimensional sandwich modifications improve the longevity of hepatocyte cultures, an imbalance of phase I/II detoxification processes typically occurs over time (Richert *et al.*, 2002). Also, the presence of an overlaid layer of extracellular matrix may present diffusion barriers for molecular stimuli (i.e., drug candidates), and the fragility of the gelled matrix may hinder scale-up within bioartificial liver devices.

Heterotypic interactions between hepatocytes and their nonparenchymal neighbors are known to be important at multiple stages *in vivo*. Liver specification from the endodermal foregut and mesenchymal vasculature during development is believed to be mediated by heterotypic interactions (Houssaint, 1980; Matsumoto *et al.*, 2001). Similarly, nonparenchymal cells of several types modulate cell-fate processes of hepatocytes under both physiologic and pathophysiologic conditions within the adult liver (Michalopoulos and DeFrances, 1997; Olson *et al.*, 1990). *In vitro*, through extensive studies initially pioneered by Guguen-Guillouzo and colleagues (1983), the viability and liver-specific functions of hepatocytes from multiple species have been shown to be stabilized for several weeks on cocultivation with a wide range of nonparenchymal cell types from within and outside the liver (Bhatia *et al.*, 1999). Furthermore, induction has been reported by nonparenchyma (both primary and immortalized) across species barriers, suggesting possible conservation of underlying mechanisms. Hepatocytes in cocultures maintain for weeks the polygonal morphology, distinct nuclei and nucleoli, well-demarcated cell-cell borders, and a visible bile canaliculi network indicative of freshly isolated cells or cells *in vivo* (Fig. 48.4). Hepatic cocultures have been utilized to investigate various physiologic and pathophysiologic processes, including host response to sepsis, mutagenesis, xenobiotic toxicity, response to oxidative stress, lipid metabolism, and induction of the acute-phase response (Bhatia *et al.*, 1999).

### Three-Dimensional Cultures

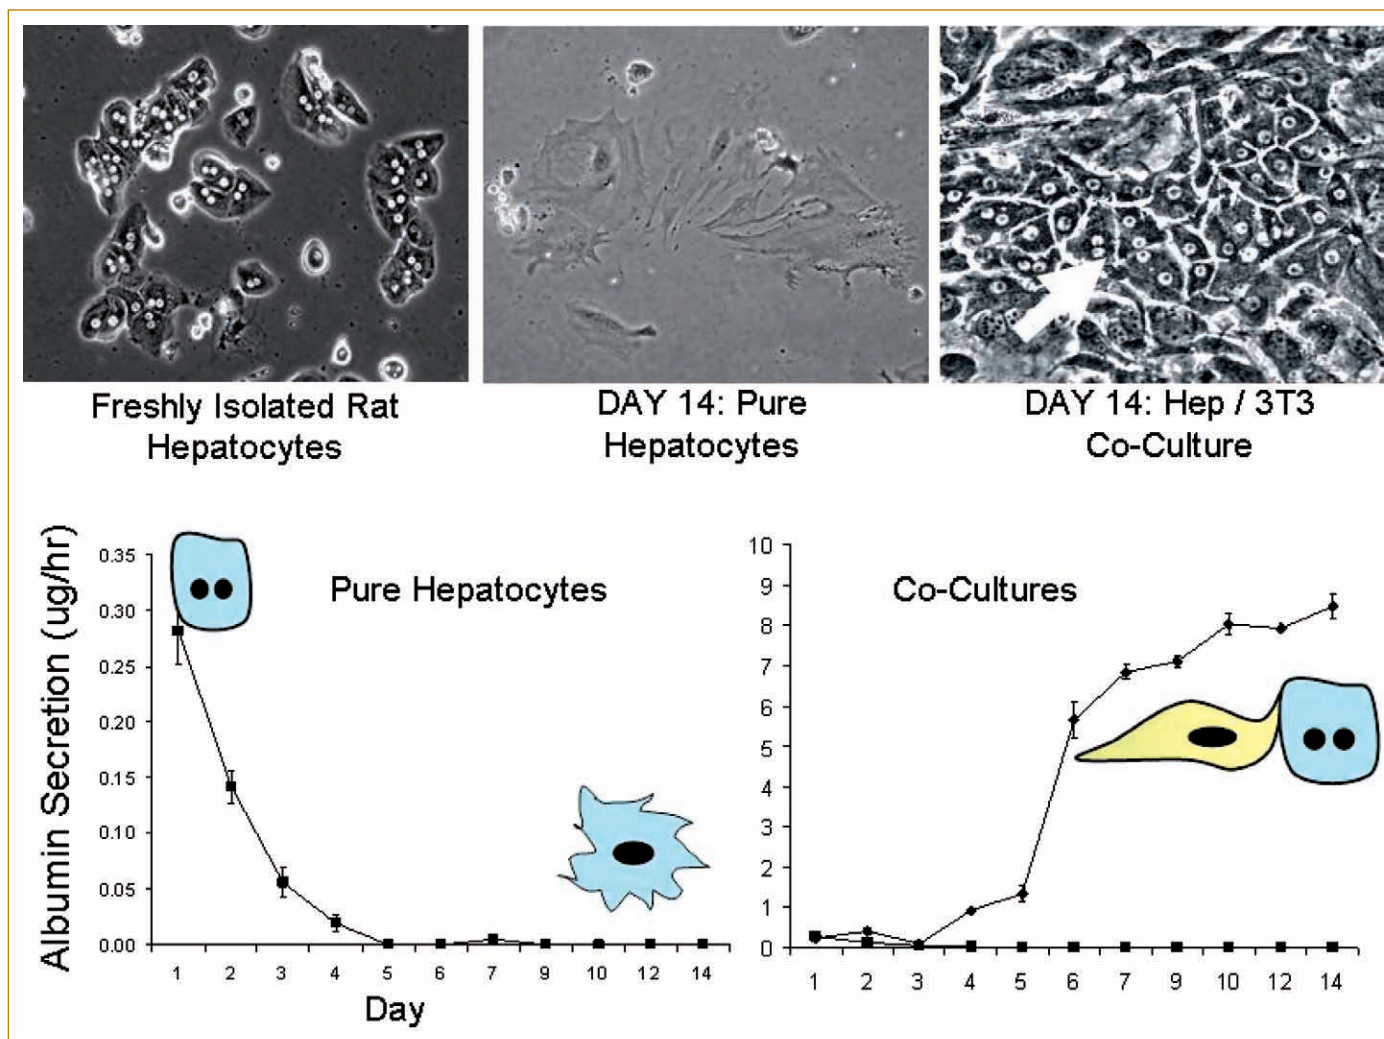

Culture of hepatocytes on substrates that promote aggregation into three-dimensional spheroids has also been extensively explored. For example, when seeded on nonadhesive surfaces such as positively charged dishes and dishes coated with liver-derived proteoglycans, hepatocytes aggregate and within one to two days form spheroidal structures with a mean diameter of ~50  $\mu\text{m}$ . Over the course of several weeks, small aggregates fuse to form larger spheroids that are 150–175  $\mu\text{m}$  in diameter (LeCluyse *et al.*, 1996). Seeding of hepatocytes into spinner flasks or on polystyrene dishes incubated on a rotary shaker allows larger spheroids to be

formed within 24 hours. Under spheroidal culture conditions, hepatocyte survival and functions are improved over standard monolayers on collagen (Landry *et al.*, 1985). The underlying mechanisms for these improvements are potentially the retention of a three-dimensional cytoarchitecture, the presence of extracellular matrix surrounding the spheroids, and the establishment of homotypic cell-cell contacts. Accordingly, static cultures of spheroids on collagen-coated dishes have been shown to disassemble, spread, and subsequently lose differentiated functions in culture (Hsiao *et al.*, 1999; Powers *et al.*, 2002). Culture of hepatocytes on a substratum coated with Matrigel (laminin-rich basement membrane extract derived from a mouse sarcoma) also induces formation of adherent three-dimensional heterogeneous spheroids and leads to retention of hepatocyte functions including CYP450 activity (Bissell *et al.*, 1987; LeCluyse, 2001). However, these effects are difficult to interpret mechanistically, since contamination of Matrigel with proteins, hormones, and growth factors has been previously reported (Guillouzo, 1998; Vukicevic *et al.*, 1992). In addition, probably the most significant drawback of Matrigel-based platforms is an imbalance of phase I/II detoxification processes (i.e., decline in CYP450 activities) that occurs over the course of a few days in culture (Richert *et al.*, 2002).

Encapsulation of spheroids has been utilized as a means to control cell-cell interactions. For example, one strategy employs hepatocyte spheroids, first suspended in a methylated collagen solution and then extruded from a needle into a terpolymer solution to form microcapsules (Chia *et al.*, 2000). A variety of other synthetic and natural scaffolds have been explored for encapsulation of single hepatocytes or hepatocyte aggregates. The development and characterization of such scaffolds are described in a subsequent section of this chapter focused on implantable constructs. In particular, spheroid cultures have been shown to be useful as the basis for both small-scale and large-scale bioreactor systems. However, the utility of spheroidal cultures can be somewhat restricted by certain properties of this configuration, including the fusion of small heterogeneous spheroids into larger structures; cell death in the center of large aggregates due to insufficient transport of nutrients and oxygen or due to bile accumulation in size-controlled, compacted spheroids; and the limited *in situ* observation of cells in aggregates. Overall, the development of novel approaches and tools to identify the important three-dimensional signals underlying hepatocyte function in spheroid structures as well as robust platforms for spheroid maintenance are active areas of research.

### Bioreactor Cultures

The development of bioreactors for hepatocellular culture has been extensively studied in the last few decades. Several different bioreactor designs have been explored for use in extracorporeal liver devices, and these are discussed in a subsequent section. Here, our focus is primarily on

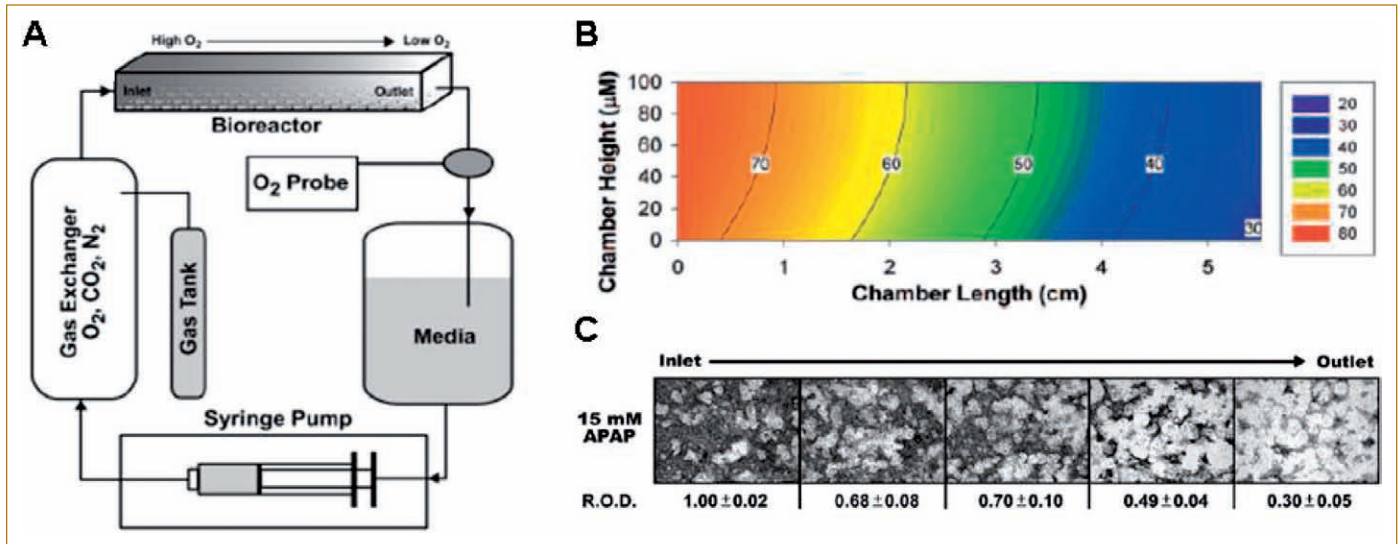

**FIG. 48.4.** The coculture effect. Isolated primary hepatocytes from a variety of species lose characteristic morphological features and liver-specific functions upon isolation from the liver. Cocultivation of hepatocytes with a wide range of nonparenchymal cells from both within and outside the liver can stabilize the hepatic phenotype. Shown here are primary rat hepatocytes cocultivated with 3T3 murine embryonic fibroblasts. Hepatocytes in cocultures maintain the polygonal morphology (see arrow in picture), visible bile canaliculi, and distinct nuclei and nucleoli as seen in freshly isolated cells and *in vivo*. On the other hand, hepatocytes in pure culture adopt a fibroblastic morphology. Furthermore, liver-specific functions (i.e., albumin secretion) decline rapidly in pure hepatocytes, whereas they are retained in cocultures for several weeks.

small-scale bioreactors that have been designed for fundamental investigations in hepatology and/or for use in drug development.

The distribution of hepatic functions along the length of the sinusoid is thought to be modulated by gradients of diverse factors such as oxygen, hormones, nutrients, and extracellular matrix molecules. Current *in vitro* models of the liver in static media conditions offer a relatively homogeneous view of liver function. Recently, a small-scale, parallel-plate bioreactor was developed that allows exposure of hepatocyte-nonparenchymal cocultures to a continuous range of oxygen tensions in order to mimic *in vivo* conditions in the liver lobule (Fig. 48.5) (Allen *et al.*, 2005). Cocultures exposed to physiologic gradients of oxygen

demonstrated regional heterogeneity of CYP2B and CYP3A expression as seen *in vivo*. Expression of these drug metabolism enzymes can be further modulated via chemical inducers and growth factors. Additionally, acetaminophen exposure induced maximal cell death in the downstream perivenous-like hepatocytes, which is consistent with the centrilobular patterns of cell death observed *in vivo*. Overall, the ability to decouple oxygen tension from gradients of other soluble stimuli and cell-cell interaction effects within this platform represents an important tool for the systematic investigation of the role of extracellular stimuli in zonation. Also, miniaturization of this bioreactor system utilizing microfluidics is currently being pursued for the high-throughput examination of drug metabolism and toxicity in

**FIG. 48.5.** Zonation and toxicity in a hepatocyte bioreactor. **(A)** Cocultures of hepatocytes and nonparenchymal cells are first created on collagen-coated glass slides and then placed in a bioreactor circuit, where the oxygen concentration at the inlet is held at a constant value. Depletion of oxygen by cells creates a gradient of oxygen tensions along the length of the chamber, similar to that observed *in vivo*. **(B)** Two-dimensional contour plot of modeled oxygen profile in the medial cross section of the reactor. Results depict the cell surface gradient formed with inlet  $pO_2$  of 76 mmHg and flow rate of 0.3 mL/min. **(C)** Bright-field images of MTT-stained (measure of cell viability), perfused cultures were acquired from five regions along the length of the slide. Images from 15 mM acetaminophen (APAP) treatment are shown, with relative optical density (R.O.D) values representing mean and standard error of mean ( $n = 3$ ). The zonal pattern of APAP toxicity seen here is consistent with that observed *in vivo*. From Allen *et al.* (2005).

addition to the further analysis of the combinatorial influence of microenvironmental factors on zoned hepatocyte functions.

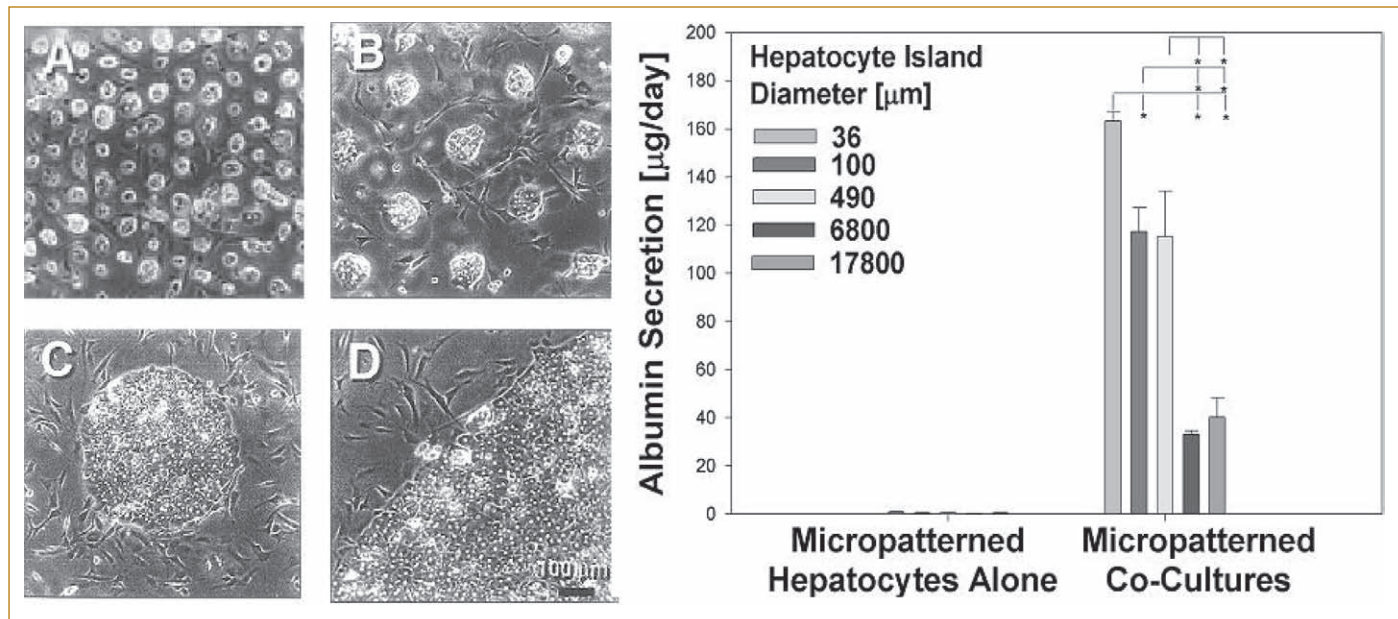

Hepatic aggregate culture in microbioreactors has also been investigated. For instance, a 1-cm<sup>2</sup> planar polymer scaffold with 900 microcontainers has been shown to be suitable for culture of uniformly sized three-dimensional hepatic aggregates (Knedlitschek *et al.*, 1999). The bottom faces of the microcontainers are modified to contain laser-drilled pores for fluid perfusion through the cellular structures. Aggregates in microcontainers retain liver-specific morphology and functions for up to two weeks. In particular, the cells secrete albumin, display active drug metabolism enzymes, and are responsive to CYP450-inducing compounds. In another platform, hepatic spheroids are cultured inside an array of microchannels created using deep reaction ion etching of silicon wafers (Sivaraman *et al.*, 2005). The wafers are combined with a cell-retaining filter and support in a bioreactor system that delivers culture medium across the top of the array and through the spheroids in each channel. Characterization via gene expression profiling, protein expression, and activity of drug metabolism enzymes indicates that the spheroids in the microfabricated bioreactor retain liver-specific characteristics for two to three weeks in culture. Inducibility of specific CYP450 enzymes via prototypic chemical inducers has also been explored in this platform, and the simultaneous examination of drug responses in six parallel reactors has been proposed (Sivaraman *et al.*, 2005).

Several other coculture bioreactor systems have been developed. For instance, a flat-plate bioreactor was used specifically to evaluate the effects of oxygenation and shear stress on bulk markers of hepatocyte function toward the fabrication of a bioartificial liver support system (Tilles *et al.*, 2001). In another perfusion system, pure rat hepatocytes and cocultures seeded on collagen-coated slides display liver-specific functions for up to two weeks and are responsive to induction of CYP450 activity by pharmaceutical compounds (Gebhardt *et al.*, 2003). In order to improve oxygen delivery to cells, a 96-well perfused microbioreactor with a gas-permeable biocompatible membrane was developed to culture collagen sandwich cocultures of hepatocytes and liver-derived nonparenchymal cells (Gebhardt *et al.*, 2003). Preliminary studies indicate that hepatocytes in this system maintain numerous important functions, including albumin and urea secretion, constitutive expression of phase I and phase II detoxification enzymes, and the inducible expression of CYP1A1. Collectively, bioreactor platforms can provide substantial control of hepatocyte culture conditions, and thus hepatocyte functions, suggesting that these systems will be key components of drug development studies as well as fundamental investigations of hepatocyte biology.

### Microtechnology Tools to Optimize and Miniaturize Liver Cultures

The ability to control tissue architecture along with cell-cell and cell-matrix interactions on the order of single-

**FIG. 48.6.** Optimization of liver-specific functions in cocultures via photolithographic micropatterning. Shown here are phase-contrast micrographs of micropatterned primary rat hepatocytes surrounded by supportive 3T3-J2 fibroblasts. Ratio of cell populations and total cell numbers were kept constant across pattern geometries, which displayed a broad range of heterotypic interface. (A) 36-μm hepatocyte islands with 90-μm center-to-center spacing (36/90); (B) 100/250; (C) 490/1230; (D) 6800/16,900. Liver-specific functions (i.e., albumin secretion) were higher in cocultures than in pure hepatocyte cultures. Furthermore, the degree of up-regulation varied with micropatterned geometry (17,800 μm represents a single hepatocyte island surrounded by fibroblasts). From Bhatia *et al.* (1999).

cell dimensions represents another important tool in the investigation of mechanisms underlying tissue development and, ultimately, the realization of tissue-engineered systems. Semiconductor-driven microtechnology tools now offer an unprecedented micrometer-scale control over cell adhesion, shape, and multicellular interactions (Folch and Toner, 2000). Thus, since the mid-1990s, microtechnology tools have emerged both to probe biomedical phenomena at relevant length scales and to miniaturize and parallelize biomedical assays (e.g., DNA microarrays, microfluidics).

In the context of the liver, a photolithographic cell-patterning technique has enabled the optimization of liver-specific functions in cocultures via engineering of the balance between homotypic (hepatocyte–hepatocyte) and heterotypic (hepatocyte–nonparenchymal) cell–cell interactions (Bhatia *et al.*, 1999). Specifically, micropatterned cocultures were created in which hepatocyte islands of controlled diameters were surrounded by supporting nonparenchymal cells (Fig. 48.6). Results indicated that rat hepatocyte–fibroblast cocultures with a maximal initial heterotypic interface (i.e., single-hepatocyte islands surrounded by supporting cells) had the highest levels of liver-specific functions as compared to other micropatterned configurations with similar cell numbers and hepatocyte-to-nonparenchymal ratios (Fig. 48.6). More recent work with primary human hepatocytes indicates that these cells are more dependent on homotypic interactions than their rat

counterparts (manuscript in preparation). As such, human hepatocyte cocultures displayed optimal functions once the appropriate balance of homotypic and heterotypic interactions was achieved. Furthermore, miniaturization of micropatterned human cocultures into a multiwell format has been performed in order to create a microscale human liver tissue model for drug development. The utility of this platform for pharmaceutical applications has been demonstrated via characterization of global gene expression, phase I/II drug metabolism, secretion of liver-specific products, drug–drug interactions, and the susceptibility to a panel of putative hepatotoxins.

As described earlier, several culture techniques have been explored for the formation of hepatic spheroids. These methods exhibit certain limitations, including an inability to immobilize the spheroids at defined locations and the heterogeneity of the structures, which can result in cell necrosis at the core of large and coalesced spheroids due to depletion of oxygen and nutrients. Recently, microfabrication and microcontact printing techniques have been combined to develop a microarray that contains immobilized spheroids of a uniform size (Fukuda *et al.*, 2005). These spheroids retained a liver-specific phenotype as assessed by the expression of liver-enriched transcriptional factors, secretion of albumin, and the presence of urea cycle enzymes.

The field of hepatic-tissue engineering continues to evolve toward creating an optimal microenvironment for

**FIG. 48.7.** Schematics of cell-based bioreactor designs. The majority of liver cell-based bioreactor designs fall into these four general categories, each with inherent advantages and disadvantages. From Allen and Bhatia (2002).

liver cells *in vitro*. Overall, it is evident that many different culture conditions can preserve at least some phenotypic features of fully functional hepatocytes. Since detailed differences can exist in these model systems, current strategies have focused on selecting a platform that is appropriate for a particular application. Although progress has been made, further work is required to obtain a more complete picture of the molecular signals that provide phenotypic stability of liver cultures. In particular, as a systems-level view of hepatocyte biology emerges, perhaps it will become evident how multiple distinct inputs influence hepatocyte function. The development of highly functional *in vitro* liver platforms will ultimately facilitate the clinical effectiveness of cell-based therapies and enable high-throughput screening of candidate drugs for liver-specific metabolism and toxicity earlier in drug discovery, which could potentially reduce development costs and help create safer drugs for patients.

## V. EXTRACORPOREAL BIOARTIFICIAL LIVER DEVICES

One of the most promising approaches for cell-based therapies for liver failure is the development of extracorporeal support devices, which, analogous to kidney dialysis systems, would process the blood or plasma of liver-failure patients. These devices are aimed principally at providing temporary support to liver-failure patients to enable sufficient regeneration of the host liver tissue or serve as a bridge to transplantation. Initial extracorporeal device designs utilized primarily nonbiological mechanisms, such as hemoperfusion, hemodialysis, plasmapheresis, and plasma exchange (Allen *et al.*, 2001). Hemoperfusion removes toxins, but also other useful metabolites, by passage of blood or plasma through a charcoal column. A modification of this approach, referred to as *hemodiadsorption* and utilized in the Liver Dialysis Unit developed by HemoCleanse, reduces direct contact with charcoal components through the

utilization of a flat-membrane dialyzer containing charcoal and exchange resin particles (Ellis *et al.*, 1999). In general, charcoal perfusion systems have been the most extensively studied nonbiological configuration, including clinical evaluation in patients with acute liver failure, although no clear survival improvement has been observed (Yarmush *et al.*, 1992). An alternative strategy, the Molecular Adsorbent Recirculating System (MARS®), uses a method termed *albumin dialysis*, in which albumin-bound toxins are cleared by interaction with an albumin-impregnated dialysis membrane (Stange *et al.*, 1993). This device has been shown to be effective for the reduction of plasma bile acids, bilirubin, and other albumin-bound toxins; results demonstrate that its use can provide clinical benefit (Sen and Williams, 2003).

In order to provide the full array of synthetic, metabolic, and detoxification functions important for the effective treatment of liver failure, which is lacking in these nonbiological schemes, biological approaches, including cross-hemodialysis, whole-liver perfusion, and liver-slice perfusion, have been explored (Yarmush *et al.*, 1992). While these methods have demonstrated some benefit, they are difficult to implement on a large scale clinically. Consequently, substantial efforts have been made toward the development of extracorporeal bioartificial liver (BAL) devices containing hepatic cells that would exhibit a myriad of critical liver functions and could be employed in a clinical setting. BAL devices that have been proposed and studied can be broadly categorized into four main types, summarized in Fig. 48.7: hollow-fiber devices, flat-plate and monolayer systems, perfusion-bed or porous-matrix devices, and suspension reactors, with each of these general designs exhibiting innate advantages and disadvantages. Overall, an effective BAL device would satisfy several important criteria, including maintenance of cell viability and hepatic functions, efficient bidirectional mass transfer, and scalability to therapeutic levels. We next discuss these issues and review recent advances in BAL device design.

## Cell Viability and Function

The components and characteristics of primary hepatocyte culture models have underscored the importance of microenvironmental signals and cellular configuration in the regulation of hepatocyte processes. Thus, the development of effective BAL systems is predicated on the appropriate incorporation of environmental and organizational cues that would enable stability of the hepatocellular component. Hollow-fiber devices, the most common BAL design, contain hepatic cells within cartridge units similar to those utilized in hemodialysis systems (J. K. Park and Lee, 2005). The hollow-fiber membranes serve as a scaffold for cell attachment and compartmentalization, although adequate nutrient transport and proper environmental stimuli are potentially limited in these configurations. Multiple modifications aimed at providing critical cellular cues have been explored. For instance, exposure of hepatocytes to plasma or blood of a sick patient may necessitate distinct alterations in hepatocyte culture conditions. Specifically, preconditioning with physiologic levels of insulin, lower than in normal culture medium, has been shown to prevent fat accumulation in hepatocytes on exposure to plasma (Chan *et al.*, 2003). Additionally, the supplementation of plasma with amino acids has been demonstrated to increase albumin and urea synthesis (Washizu *et al.*, 2000). An important role has also been suggested for homotypic cell–cell interactions. Single-cell suspensions of hepatocytes have been used in some devices because of their advantageous transport characteristics, although these systems quickly lose metabolic activity (Margulis *et al.*, 1989). Due to the enhanced function of hepatocyte spheroids relative to dispersed cells, many device configurations contain either attached or encapsulated hepatocyte aggregates (J. K. Park and Lee, 2005). For example, the original HepatAssist system, previously developed by Circe Biomedical, was a hollow-fiber device containing microcarrier-attached porcine hepatocyte aggregates within the extracapillary space (Rozga *et al.*, 1993). Collagen gel entrapment of hepatocyte aggregates has also been added to some hollow-fiber designs to improve function, and many perfusion-bed systems integrate hepatocyte aggregates within a polymeric network of pores or capillaries (van de Kerkhove *et al.*, 2004). Furthermore, encapsulation of preformed hepatocyte spheroids within calcium-alginate beads has been explored as a means to promote hepatocyte stability while simultaneously providing an immunoisolation barrier (J. K. Park and Lee, 2005).

The inclusion of other stable *in vitro* model characteristics has similarly been investigated. For instance, a fundamental component of the modular extracorporeal liver support (MELS) system, developed by Gerlach and coworkers, is the spontaneous aggregation of hepatocytes in coculture with nonparenchymal cells, resulting in the formation of tissue-like organoid structures (Gerlach, 1996). Bile

canaliculi and bile-duct structures as well as matrix deposition have been observed in this system, which utilized both porcine cells and primary human hepatocytes isolated from livers unsuitable for transplant (Sauer *et al.*, 2002). Platforms based on collagen gel “sandwich culture,” a stable hepatocyte-only culture configuration, have also been developed (De Bartolo *et al.*, 2000).

## Mass Transfer

Bidirectional mass transfer is another primary consideration in the design of BAL systems and is required to provide vital nutrients to the incorporated cells and simultaneously allow export of therapeutic cellular products. Device configuration determines both the convective and the diffusive properties of the system, thereby dictating the exchange of soluble components. In particular, diffusion resistance is often a major constraint in BAL devices. Factors commonly limiting diffusive transport are membrane structures, collagen gels, and nonviable cells. For example, semi-permeable membranes are often utilized in BAL devices in order to enable selectivity in the size of exchanged factors. Inherent to most hollow-fiber devices, but also utilized in some flat-plate and perfusion-bed systems, such membranes with a designated molecular weight cutoff act to prevent the transport of immunologic components and larger xenogeneic substances while maintaining transport of carrier proteins such as albumin. Although clearly not ideal, in order to maximize mass transfer, immunologic barriers have been eliminated from some device designs (van de Kerkhove *et al.*, 2002), with the assumption that the short duration of contact with xenogeneic cells will result in minimal immunological complications. Perfusion-bed systems allow for enhanced mass transfer due to the direct contact with the perfusing media, although fluid flow distribution is highly contingent on the type of packing material. Encapsulation of dispersed or aggregated cells represents another strategy for immunoisolation but can increase diffusion resistance (Dixit and Gitnick, 1998; Yanagi *et al.*, 1989). The development of novel methods for the microencapsulation of hepatocytes is an active research area and is discussed in more detail in the implantable applications section of this chapter.

Oxygen tension is an important mediator of hepatocyte function (Bhatia *et al.*, 1996; Holzer and Maier, 1987; Nauck *et al.*, 1981); thus, the improved regulation of oxygen delivery is a major goal of many recently developed BAL platforms. Strategies have included the incorporation of additional fiber components that carry oxygen directly into the device (Gerlach *et al.*, 1994; Wolfe *et al.*, 2002), and this approach has been employed in systems shown to be effective for the maintenance of certain hepatocyte functions (Gerlach *et al.*, 1994). In contrast with other designs, flat-plate geometries can be perfused in a relatively uniform manner, although this configuration may result in the exposure of cells to shear stress, causing deleterious effects on

cellular function (De Bartolo *et al.*, 2000; Kan *et al.*, 1998; Taguchi *et al.*, 1996; Tilles *et al.*, 2001). Several approaches for minimizing shear-stress exposure in the flat-plate geometry have been explored, including the fabrication of grooved substrates for shear protection as well as the integration of adjacent channels separated by a gas-permeable membrane as a means to decouple oxygen exchange and volumetric flow rate (J. Park *et al.*, 2005; Roy *et al.*, 2001; Tilles *et al.*, 2001). Notably, as discussed earlier, oxygen has been implicated in the heterogeneous distribution of hepatocyte functions along the liver sinusoid, and this distribution can be recapitulated *in vitro* within a bioreactor system (Allen and Bhatia, 2003). The eventual incorporation of oxygen gradients, as well as gradients of other, diverse stimuli, such as hormones and growth factors, into BAL designs could provide a means to simulate more closely the range of hepatocyte functions exhibited *in vivo* and to further enhance the effectiveness of BAL devices.

### Scale-Up

The successful clinical implementation of any BAL device is dependent on the ability to scale the device to a level that provides effective therapy. Hepatocyte transplantation experiments in humans as well as rat models have demonstrated some improvement in various blood parameters following the transplantation of cell numbers representing on the order of 1–10% of total liver mass (Bilir *et al.*, 2000; Eguchi *et al.*, 1997; Gupta and Chowdhury, 2002; Strom *et al.*, 1999). However, engraftment efficiency and potential indirect influences on the regeneration of the native liver are important variables in the transplantation setting and can make it difficult to determine the direct effect and functional capacity of transplanted cells. BAL devices that have been tested clinically have used approximately  $0.5 \times 10^9$  to  $1 \times 10^{11}$  porcine hepatocytes or  $4 \times 10^{10}$  C3A hepatoblastoma cells (van de Kerkhove *et al.*, 2004). The target capacity of most current BAL designs is approximately  $1 \times 10^{10}$  hepatocytes, representing roughly 10% of total liver weight. Increasing cartridge size and the use of multiple cartridges have been utilized to scale-up hollow-fiber-based systems. For example, the recently developed HepatAssist-2 (<http://www.arbios.com>) system can contain  $1.5 \times 10^{10}$  hepatocytes, three times the capacity of the original version. Perfusion systems or devices utilizing encapsulated cells can be scaled fairly easily to the desired size; however, such expanded configurations normally present a large priming or dead volume. Stacked-plate designs have been suggested as a means to scale-up flat-plate systems, although these modifications may introduce channeling effects and heterogeneous flow distribution (Allen *et al.*, 2001). Since hepatocytes exhibit substantial metabolic activity, oxygen delivery is a critical parameter in the scaling up of BAL devices. Accordingly, in addition to improvements in gas exchange, methods to prevent hepatocyte apoptosis resulting from hypoxic injury have also been investigated (Nyberg *et al.*, 2000).

Overall, the development of BAL devices exhibiting therapeutic levels of function is a major challenge, and developing modifications aimed at further improving the capacity and efficiency of these systems is a central goal in the field.

### Regulation and Safety

Similar to other tissue-engineering-based therapies, the regulation of BAL devices is complex, due to the hybrid nature of these systems. Currently, BAL devices are being regulated as drugs through the Center for Biologics and Evaluation Research of the Food and Drug Administration. The primary safety concerns for BAL systems are similar to those for other cell-based therapies, such as escape of tumorigenic cells, immune reactions to foreign antigens, and xenozoonosis. Other potential complications generally associated with extracorporeal blood treatment include hemodynamic, metabolic, and hypothermia-related abnormalities as well as problems linked with catheterization and anticoagulation (Sen and Williams, 2003). In order explicitly to prevent escape of tumorigenic cells, such as the C3A cell line used in the ELAD system, downstream filters have been added to BAL designs (Millis *et al.*, 2002), an approach that is generally acknowledged as an adequate precautionary measure.

With regard to the utilization of porcine hepatocytes, there is some evidence for the presence of antibodies directed against porcine antigens in the serum of patients treated with BAL devices (Baquerizo *et al.*, 1997). However, the clinical significance of these findings remains unclear, since high titers are not observed until one to three weeks, for IgM and IgG isotypes, respectively. These results suggest that immune rejection may not be a significant problem in the context of BAL therapy, except in cases of repetitive treatments. Still, appropriate modifications through cell sourcing or device design aimed at limiting immunologic complications would likely be important in the expansion of BAL treatment options to chronic-liver-disease patients and patients with repetitive episodes of acute decompensation. As mentioned earlier, exposure to porcine cells can also represent a risk of xenozoonotic transmission of PERV, ubiquitous in the genome of bred pigs. PERV has been shown to infect human cell lines *in vitro* (Patience *et al.*, 1997), although studies examining transmission to BAL-treated patients have not demonstrated any evidence of infection (Pitkin and Mullon, 1999). Although specific transmission of PERV may not occur during the course of BAL therapy, the use of xenogeneic cells in BAL devices will always incur a note of caution.

### Ongoing Clinical Trials

A number of BAL devices have been tested clinically. The characteristics of these systems are provided in Table 48.2. Important practical issues include the use of whole blood versus plasma, the type of anticoagulation regiment, and the utilization of fresh or cryopreserved cells. The use of whole blood exhibits the advantage of including oxygen-

**Table 48.2.** Characteristics of eight bioartificial liver systems

<i>BAL system</i>	<i>Configuration</i>	<i>Cell source/amount</i>	<i>Trial phase</i>	<i>Comments</i>
HepatAssist (Circe Biomedical, Lexington, MA)	Hollow fiber, polysulphone; microcarrier attached	Cryopreserved porcine ( $5\text{--}7 \times 10^9$ )	II/III	Plasma, citrate anticoagulation, 0.15–0.20- $\mu\text{m}$ pore size, 6 h/session for 1–5 days
ELAD (Vital Therapies, La Jolla, CA)	Hollow fiber, cellulose acetate; large aggregates	C3A human cell line (200–400 g)	II	Plasma, heparin anticoagulation, 120-kDa cutoff, continuous up to 107 h
MELS (Charitè Virchow, Berlin, Germany)	Hollow fiber, interwoven, multicompartiment; tissue organoids	Freshly isolated porcine or human (250–500 g)	I/II	Plasma, heparin anticoagulation, 400 kDa cutoff, continuous up to 3 d
BLSS (Excorp Medical, Oakdale, MN)	Hollow fiber, cellulose acetate; collagen gel entrapped	Freshly isolated porcine (70–120 g)	I/II	Whole blood, heparin anticoagulation, 100-kDa cutoff, 12 h/session for up to 2 sessions
RFB-BAL (Univ. of Ferrara, Italy)	Radial flow bioreactor; aggregates	Freshly isolated porcine (200–230 g)	I/II	Plasma, heparin/citrate anticoagulation, 1- $\mu\text{m}$ polyester screen, 6–24-h treatments
AMC-BAL (Univ. of Amsterdam, the Netherlands)	Nonwoven polyester matrix, spirally wound; aggregates	Freshly isolated porcine ( $10 \times 10^9$ )	I	Plasma, heparin anticoagulation, direct cell–plasma contact, up to 18 h/session for up to 2 sessions
LiverX-2000 (Algenix Inc., Minneapolis, MN)	Hollow fiber; collagen entrapped	Freshly isolated porcine (40–80 g)	I	Whole blood, heparin anticoagulation
HBAL (Nanjing Univ., Nanjing, China)	Hollow fiber; polysulfone; adsorption column	Freshly isolated porcine ( $10 \times 10^9$ )	I	Plasma, 100-kDa cutoff, one to two 6-h treatments

containing erythrocytes; however, undesirable leukocyte activation and cell damage may arise. In contrast, perfusion of plasma prevents hematopoietic cell injury, but the solubility of oxygen in plasma devoid of oxygen carriers is quite low. Furthermore, heparin coagulation is normally used in BAL systems, although deleterious effects of heparin exposure on hepatocyte morphology and function have been suggested (Stefanovich *et al.*, 1996). Regarding cell source, freshly isolated hepatocytes represent the ideal condition, due to the documented decrease in hepatocyte function following cryopreservation (Chesne *et al.*, 1993; De Loecker *et al.*, 1990). Yet cryopreservation enables flexibility in the timing of therapies; thus, methods to enhance cryopreserved hepatocyte function are actively being explored (Sosef *et al.*, 2005).

The design of clinical trials for BAL devices poses a significant challenge. In particular, liver failure progression is highly variable and etiology dependent. Additionally, one of the major manifestations of liver failure, hepatic encephalopathy, is difficult to quantify clinically. As a result, patients in clinical trials must be randomized while still controlling for the stage at which support was initiated as well as etiology. Similarly, the determination of the relevant control therapy can be difficult. Ideally, in order to minimize non-specific effects of extracorporeal treatment, a nonbiological control such as veno-venous dialysis would be utilized. Another challenge is the choice of clinical endpoint. Most clinical trials utilize endpoints of 30-day survival and 30-day transplant-free survival; however, trials can often be confounded by the fact that acute-liver-failure patients receive transplants variably, depending on organ availability and the eligibility criteria in place at a given center. Furthermore, interpretation of the specific role of incorporated live, functional hepatocytes can be complicated by the presence of nonbiological adjuncts, such as charcoal perfusion, in some designs. A direct comparison of the effect of nonbiological systems alone, dead or nonhepatocyte cells, and live hepatocytes would provide substantial insight concerning the effectiveness of the cellular components, particularly given that dead hepatocytes and nonhepatocyte cells have been shown to offer some survival benefit in various animal models of acute liver failure (Makowka *et al.*, 1980). Notably, the ability to assess more accurately the viability and function of cells during BAL treatment would be a major advance. Such information would be crucial in determining treatment time and the potential requirement for device replacement, both important considerations due to the instability of hepatocellular function in many contexts and the demonstrated detrimental effect of plasma from liver-failure patients on cultured hepatocytes (Sakai *et al.*, 1996). Finally, even if clinical trials of current BAL devices do not prove efficacy, information obtained from these studies coupled with improvements in cell sourcing and functional stabilization will represent the foundation for the next generation of devices.

## VI. CELL TRANSPLANTATION

In addition to temporary extracorporeal support, the development of cell-based therapies for liver treatment aimed at the eventual replacement of damaged or diseased tissue is an active area of investigation. One potential cell-based approach is the transplantation of isolated mature hepatocytes. In experiments utilizing rodent models, transplanted hepatocytes were demonstrated to exhibit substantial proliferative capacity and the ability to replace diseased tissue under some limited conditions (Overturf *et al.*, 1997; Rhim *et al.*, 1994; Sokhi *et al.*, 2000). The *in vivo* proliferation of transplanted hepatocytes is highly dependent on the presence of an adequate regenerative environment. In animal models, discussed in more detail later in this chapter, regenerative stimulation is provided by transgenic injury, partial hepatectomy, portocaval shunting, or the administration of hepatotoxic agents prior to cell transplantation. However, these approaches would be difficult to adapt to a clinical setting. For cell delivery, several distinct approaches have been explored, including intrasplenic or intraperitoneal injection and direct injection into peripheral veins, the portal vein, or the splenic artery. Major limitations of isolated cell transplantation include the inefficient engraftment and limited survival of transplanted hepatocytes, which has been collectively reported at only 20–30% of injected cells (Gupta *et al.*, 1999). Several studies have demonstrated methods to improve engraftment and enhance the selective proliferation of transplanted hepatocytes (Guha *et al.*, 1999; Laconi *et al.*, 1998; Mignon *et al.*, 1998), although, analogous to regeneration models, the clinical utility of these approaches remains to be determined. The time for engraftment and proliferation of transplanted hepatocytes also can create a substantial lag time [48 h in one study (Bilir *et al.*, 2000)] before clinical benefit is observed, which could restrict the utility of cell transplantation for certain clinical conditions, such as fulminant hepatic failure. Consequently, at least in the immediate future, hepatocyte transplantation may provide the maximum clinical benefit for patients with hereditary metabolic disorders, which can be effectively treated with relatively little liver mass (2%–5%).

Similar to other cell-based approaches, the feasibility of hepatocyte transplantation is constrained by the availability of allogeneic human hepatocytes. Only a limited supply of human hepatocytes is currently available from collagenase perfusion of organs regarded as inappropriate for transplantation. Accordingly, many other cell source options are under investigation, as discussed earlier. For example, immortalization has been explored as a means to promote hepatocyte proliferation and survival, although tumor development is a major concern with this approach. Numerous stem cell or progenitor cell populations are also being examined as an alternative to mature hepatocytes in the cell transplantation context. Significant efforts have been focused on prospectively identifying intrahepatic stem cells

that participate in liver regeneration, specifically, the possible role of bone marrow-derived cells. Although it has become clear that bone marrow-derived hepatocytes are rare under most circumstances and likely arise through cell fusion (Thorgeirsson and Grisham, 2006), if sufficiently optimized, the potential utility of bone marrow cells as a gene delivery vehicle for liver repair remains an intriguing option. Overall, elucidation of the mechanisms regulating the proliferation and hepatic differentiation of various stem and progenitor cell populations could lay the groundwork for the development of robust cell-based liver transplantation therapies.

VII. THREE-DIMENSIONAL HEPATOCELLULAR SYSTEMS: DEVELOPMENT OF IMPLANTABLE THERAPEUTIC CONSTRUCTS

The development of implantable cellular platforms is another promising cell-based therapy for liver disease. Similar in principle to cell transplantation, in that hepatocytes are transplanted to perform liver functions, this approach is characterized by the immobilization or encapsulation of hepatocytes, using biomaterials in order to improve cellular survival and function. Notably, implantation of preformed hepatocellular constructs could potentially represent an approach to avoid many of the limitations inherent in cell transplantation strategies, namely inefficient engraftment, the required repopulation advantage of donor cells, and the resultant lag phase before clinical benefit. Implantable systems can generally be separated into two categories: (1) platforms based on acellular scaffolds, which serve as a substrate for cellular attachment, and (2) platforms in which hepatic cells are fully encapsulated within the biomaterial scaffold.

Acellular Scaffolds for Cellular Attachment

Hepatocytes are known to be anchorage dependent, and initial experiments examining implantable approaches were formulated based on the hypothesis that providing a substrate for cellular attachment would enhance function. For example, hepatocytes were attached to collagen-coated dextran microcarriers and transplanted intraperitoneally into animals exhibiting two different model genetic disorders (Demetriou *et al.*, 1986). Microcarriers were found to serve as an adequate platform for cell attachment and enhanced survival and function of the transplanted hepatocytes in both model systems. As a result of these studies, microcarriers were utilized to retain and promote the function of porcine hepatocytes in the HepatAssist BAL device described earlier. Various other microcarrier chemistries have been explored for hepatocyte culture, including cellulose (Kasai *et al.*, 1992; Kino *et al.*, 1998), gelatin (Tao *et al.*, 2003), and gelatin/chitosan composite (Li *et al.*, 2004). The potential effects of microcarrier architecture, such as a

Table 48.3. Scaffolds utilized for hepatocellular constructs

Category	Compositions
Natural	Collagen, chitosan, collagen/chitosan composites, alginate, alginate composites, biomatrix, peptides, hyaluronic acid, fibrin, gelatin
Synthetic	PLLA, PLGA, PLLA/PLGA composite, PGA, PEG, PCL, PET, PVA

Abbreviations: PLLA, poly(L-lactic acid); PLGA, poly(DL-lactide-co-glycolide); PGA, polyglycolic acid; PEG, poly(ethylene glycol); PCL, polycaprolactone; PET, poly(ethylene terephthalate); PVA, polyvinyl alcohol.

porous surface topography, on hepatocyte attachment and aggregation have also been investigated (Tao *et al.*, 2003). Such systems share homology with acellular porous scaffolds, utilized in many fields of tissue engineering.

A central tenet of many implantable tissue-engineering approaches is the use of porous scaffolds that provide mechanical support, often in conjunction with cues for growth and morphogenesis. Collectively, the porosity and biodegradability of these constructs enables the integration of the implant with host tissue, particularly the host blood vessels. Proposed hepatocellular constructs have utilized scaffolds of diverse natural and synthetic compositions (Table 48.3). Collagen or various alginate and chitosan composites are the most commonly used natural/biologically derived scaffold materials for hepatocyte culture. Collagen sponge structures have been proposed as platforms for tissue-engineered constructs in a wide array of cellular systems as well as substrates for promoting wound repair. In a study examining hepatocyte interaction with collagen scaffolds exhibiting a range of pore sizes (10–82 μm), pore size was found to be an important factor regulating cell spreading and cell–cell interactions, both of which can influence hepatocyte functions (Ranucci *et al.*, 2000). In addition, alginate scaffolds with pore sizes of approximately 100 μm have been shown to be well suited for encouraging spheroidal aggregation of hepatocytes, due to the weakly adhesive nature of the material (Glicklis *et al.*, 2000). Spheroid formation in this platform acts to promote hepatocyte stabilization, an effect that was described in detail earlier. Adaptations on the pure alginate formulation, such as an alginate/galactosylated chitosan/heparin composite system (Seo *et al.*, 2006), have been reported to enhance aggregation and cell viability further (Chung *et al.*, 2002; Haque *et al.*, 2005; Maguire *et al.*, 2006; Seo *et al.*, 2006). Although natural scaffold materials exhibit robust biocompatibility and some are capable of mediating substantial cell attachment (e.g., collagen), biodegradable synthetic polymers that offer flexibility in structure, mechanical prop-

erties, and degradation kinetics have also been investigated for use in hepatic-tissue-engineering applications.

Polyesters such as poly(L-lactic acid) (PLLA) and poly(DL-lactide-co-glycolide) (PLGA) are the most common synthetic polymers utilized in the generation of porous tissue-engineering constructs, due to their biocompatibility, biodegradability, and highly versatile properties. These systems have been shown to be supportive for hepatocyte culture and have been used as scaffolds for hepatocyte transplantation. For example, a composite PLLA/PLGA scaffold was demonstrated to support long-term engraftment of hepatocytes on mesenteric transplantation in a rodent injury model (Mooney *et al.*, 1997). Of note, PLLA and PLGA exhibit distinct hydrolysis kinetics; thus, the adjustment of the relative contribution of these components has been illustrated as a means to regulate degradation time. Furthermore, modifications of PLGA scaffolds have been shown to improve functionality. Specifically, infiltration of hydrophilic polyvinyl alcohol (PVA) into PLGA scaffolds was noted to enhance hepatocyte seeding (Mooney *et al.*, 1995), and alkali hydrolysis and extracellular matrix coating of PLGA constructs can improve hepatocyte attachment (Fiegel *et al.*, 2004; Hasirci *et al.*, 2001; Nam *et al.*, 1999). Other modifications of polymer scaffold chemistries, such as the addition of biologically active factors, are discussed in more detail later. In order to obtain a homogeneous cellular distribution, porous, acellular scaffolds are normally seeded utilizing gravity, centrifugal forces, or convective flow or through the recruitment of cells with chemokines or growth factors. However, incorporation of hepatocytes into scaffolds is hindered by their relatively immotile nature and their limited proliferation *ex vivo*. Also, while porous scaffold systems continue to be explored for use in liver constructs, many of these scaffold architectures are essentially two-dimensional surfaces, from the hepatocyte perspective, perhaps limiting their utility toward the full recapitulation of three-dimensional cues, which will likely be important for certain hepatocyte functions, such as the coordination of bile drainage.

### Hepatocellular Encapsulation Platforms

The development of highly functional implantable liver systems is contingent on the generation of fully populated, thick constructs that concurrently promote three-dimensional conformations, hepatocyte stability, and the transport of nutrients and large macromolecules. Consequently, as alternatives to macroporous scaffold systems, approaches aimed at the efficient and homogeneous encapsulation of hepatocytes within a fully three-dimensional structure have been explored. In particular, hydrogels that exhibit high water content and thus mechanical properties similar to those of tissues are widely utilized for various tissue-engineering applications, including hepatocellular platforms (Drury and Mooney, 2003). Similar to preformed acellular scaffolds, encapsulation schemes have employed

various natural and synthetic chemistries (Table 48.3). Natural platforms have been based primarily on biologically derived extracellular matrix, such as collagen gel (Dixit *et al.*, 1990), peptides (Semino *et al.*, 2003), and alginate and alginate-based composites (Haque *et al.*, 2005; Hirai *et al.*, 1993; Maguire *et al.*, 2006; Miura *et al.*, 1986). In general, microencapsulation of hepatocytes in these types of systems has been shown to facilitate hepatocyte aggregation and to promote function. For instance, alginate-based encapsulation platforms have been demonstrated to support hepatocyte spheroid culture while simultaneously providing an immunoisolation barrier (Haque *et al.*, 2005; Hirai *et al.*, 1993; Miura *et al.*, 1986), and consequently they have been proposed for use in both implantable constructs and BAL devices.

Synthetic hydrogels, such as poly(ethylene glycol) (PEG)-based systems, have become increasingly utilized in tissue-engineering applications, due to their hydrophilicity and resistance to protein adsorption, their biocompatibility, and the ability to customize these gels through the modification of chain length and the addition of bioactive elements (Peppas *et al.*, 2000). Also, such synthetic hydrogels can be polymerized in the presence of cells, thereby generating three-dimensional constructs with a uniform cellular distribution throughout the network. PEG-based hydrogels have been used for the encapsulation of a diverse array of cell types. Initial studies examining PEG hydrogel encapsulation of hepatic cells utilized immortalized hepatocytes or hepatoblastoma cell lines (Itle *et al.*, 2005; V. A. Liu and Bhatia, 2002), demonstrating the compatibility of these cell types with this system. However, encapsulation of primary hepatocytes may necessitate distinct hydrogel conditions. Accordingly, recent experiments have begun to explore the potential utility of PEG hydrogels as a three-dimensional platform for primary hepatocytes, including the important parameters influencing encapsulated hepatocyte function. For example, following encapsulation in PEG hydrogels, primary hepatocytes exhibit a rapid and substantial decrease in viability (manuscript in preparation). However, analogous to strictly two-dimensional coculture systems, coculture with 3T3 fibroblasts greatly improved the maintenance of hepatocyte survival and function. In addition, PEG chain length determines the mesh size and diffusive characteristics of the hydrogel network, and culture within 10% (w/v) 20-kDa PEG hydrogels was shown to facilitate the release of secreted albumin, a critical parameter for an implantable construct as well as the accurate assessment of encapsulated hepatocyte function. Incorporation of liver progenitor cells into PEG hydrogel constructs has similarly been investigated. Specifically, homotypic cell-cell interactions were recently demonstrated to be important for the maintenance of BMEL cell viability in PEG hydrogels, and the efficient differentiation of these cells toward the hepatocyte lineage was compatible with this platform (Fig. 48.2). Overall, synthetic hydrogel systems represent promising platforms for implantable constructs as well as models for the *in vitro*

investigation of hepatocellular responses within a three-dimensional context.

### Modifications in Scaffold Chemistry

Although synthetic polymer scaffolds offer many advantages, these systems are often limited in their capacity to mediate aspects of hepatocyte function, such as cell adhesion. Yet the inert nature of synthetic systems could also be viewed as an advantage, by facilitating the controlled incorporation of biologically active elements aimed at regulating distinct aspects of cellular function. Multiple diverse approaches have been explored for modulating hepatocyte interactions with synthetic platforms. These include addition of extracellular matrix molecule coatings (Fiegel *et al.*, 2004; Hasirci *et al.*, 2001) and the incorporation of various sugar residues, such as lactose and heparin (Gutsche *et al.*, 1996), and galactose (Chua *et al.*, 2005; T. G. Park, 2002), all of which have been implicated in improving hepatocyte adhesion and function within polymer scaffolds. Similarly, addition of poly(*N*-*p*-vinylbenzyl-4-*O*- $\beta$ -D-galactopyranosyl-D-glucosamine) (PVLA) to PLLA scaffolds has been shown to improve hepatocyte adhesion due to its integral hydrophilic oligosaccharide residue (Karamuk *et al.*, 1999; J. S. Lee *et al.*, 2005; Mayer *et al.*, 2000). Furthermore, incorporation of epidermal growth factor (EGF) into PET fabric scaffolds was suggested to improve rates of hepatocyte aggregation (Mayer *et al.*, 2000). Taken together, these examples highlight modifications of the polymer scaffold backbone through either nonspecific adsorption or chemical conjugation of biological factors that subsequently act to influence hepatocyte processes. As an alternative to the integration of entire biomolecules, polymer scaffolds can also be conjugated with bioactive peptide sequences.

The addition of adhesive peptides that interact with integrin receptors has been extensively utilized to promote cell attachment in polymer systems. In particular, inclusion of RGD peptides within biomaterial scaffolds has been shown appreciably to influence the adhesion and function of a diverse array of cell lines and primary cell populations. Regarding hepatic cells, grafting of RGD peptides to PLLA scaffolds has been shown to enhance hepatocyte attachment (Carlisle *et al.*, 2000). The presence of RGD peptides has also been suggested to affect hepatocyte functions within hydrogel networks. For instance, RGD conjugation significantly improved the long-term stability of primary hepatocyte function within PEG hydrogels (manuscript in preparation). The additional incorporation of adhesive peptides that bind other integrins may serve as a way to modulate and enhance hepatocyte function further within synthetic polymer substrates. Moreover, although not yet applied to hepatocellular systems, the integration of matrix metalloproteinase-sensitive peptide sequences into hydrogel networks as degradable linkages has been shown to enable cell-mediated remodeling of the gel (Lutolf *et al.*, 2003; Mann *et al.*, 2001; Seliktar *et al.*, 2004). The capacity to

modify biomaterial scaffold chemistry through the introduction of biologically active factors will likely enable the finely tuned regulation of cell function and interactions with host tissues important for implantable systems.

### Controlling Three-Dimensional Architecture and Cellular Organization

In addition to alterations in scaffold chemistry, another approach for improving the functionality of tissue engineered constructs is based on the premise of more closely mimicking *in vivo* microarchitecture. The 3D architecture of native tissues influences not only cellular function, but also mechanical properties and the interfacing of tissue units with the microcirculation. The ability to fabricate cellular scaffolds with a highly defined structure would facilitate the recapitulation of the appropriate micro-scale environment for cell viability and function as well as the integration of macro-scale properties dictating mechanical characteristics, nutrient delivery, and the coordination of multicellular processes. Recent application of CAD-based manufacturing technologies to biomaterial scaffold fabrication has enabled multiscale regulation of scaffold features.

CAD-based rapid prototyping strategies that have been applied to polymer scaffold fabrication exploit multiple modes of assembly, including fabrication using heat, light, adhesives, or molding; these techniques have been extensively reviewed elsewhere (Tsang and Bhatia, 2004). For example, three-dimensional printing with adhesives combined with particulate leaching has been utilized to generate porous PLGA scaffolds for hepatocyte attachment (S. S. Kim *et al.*, 1998b), and microstructured ceramic (Petronis *et al.*, 2001) and silicon scaffolds (Kaihara *et al.*, 2000; Ogawa *et al.*, 2004) have been proposed as platforms for hepatocyte culture. Furthermore, molding and microsyringe deposition have been demonstrated to be robust methods for fabricating specified three-dimensional PLGA structures toward integration into implantable systems (Vozzi *et al.*, 2003).

Microfabrication techniques have similarly been employed for the generation of patterned cellular hydrogel constructs. For instance, microfluidic molding has been used to form biological gels containing cells into various patterns (Tan and Desai, 2003). In addition, syringe deposition in conjunction with micropositioning was recently illustrated as a means to generate patterned gelatin hydrogels containing hepatocytes (Wang *et al.*, 2006). Patterning of synthetic hydrogel systems has also recently been explored. Specifically, the photopolymerization property of PEG hydrogels enables the adaptation of photolithographic techniques to generate patterned hydrogel networks. In this process, patterned masks printed on transparencies act to localize the UV exposure of the prepolymer solution and, thus, to dictate the structure of the resultant hydrogel. The major advantages of photolithography-based techniques for patterning of hydrogel structures are its simplicity and flexibility. Photopatterning has been employed to surface pattern

**FIG. 48.8.** Multiscale regulation of hydrogel structure and cellular organization. **(A)** Hydrogel photopatterning was utilized to generate a multilayer branched construct to facilitate adequate perfusion of encapsulated cells. Scale bar, 500  $\mu\text{m}$ . **(B)** Encapsulated hepatocytes were initially patterned in approximately 1-mm-diameter islands, followed by the polymerization of a surrounding hydrogel network containing encapsulated fibroblasts. Hepatocyte-specific glycogen staining (purple-magenta) demonstrates the localization of these hepatocyte domains. Scale bar, 250  $\mu\text{m}$ . **(C)** Hepatocytes organized via electropatterning were entrapped in islands by photopatterning and then surrounded by electropatterned encapsulated fibroblasts. Glycogen staining (purple-magenta) was performed on these dual patterned constructs. Scale bar, 50  $\mu\text{m}$ .

biological factors (Hahn *et al.*, 2006), produce hydrogel structures with a range of sizes and shapes (Beebe *et al.*, 2000; Revzin *et al.*, 2001), as well as build multilayer cellular networks (V. A. Liu and Bhatia, 2002). Consequently, hydrogel photopatterning technology is ideally suited for the regulation of scaffold architecture at the multiple length scales required for implantable hepatocellular constructs. As a demonstration of these capabilities, photopatterning of PEG hydrogels was recently utilized to generate hepatocyte/fibroblast coculture hydrogels with a defined organization (Fig. 48.8) (manuscript in preparation). Also, the additional combination of photopatterning with dielectrophoresis-mediated cell patterning enabled the construction of hepatocellular hydrogel structures with an organization defined at the cellular scale (Fig. 48.8). Of note, perfusion of hepatocellular constructs has been implicated in the improvement of hepatocyte functions (S. S. Kim *et al.*, 1998a; T. G. Park, 2002). Photopatterning of PEG hydrogels containing hepatocyte/fibroblast cocultures into a three-dimensional branched network (Fig. 48.8) and culture under flow conditions enhanced encapsulated hepatocyte function (manuscript in preparation). Overall, the ability to dictate scaffold architecture coupled with other advances in scaffold material properties, chemistries, and the incorporation of bioactive elements will serve as the foundation for the future development of improved tissue-engineered liver constructs that can be customized spatially, physically, and chemically.

### Host Interactions

Further challenges in the design of therapeutic implantable liver devices are more specifically associated with the

interactions with the host environment. These include issues related to vascularization, remodeling, the biliary system, and immunologic considerations. Notably, a significant challenge for the design of implantable liver constructs is the need to overcome transport limitations within the grafted construct due to the lack of functional vasculature. Within the normal liver environment, hepatocytes are supplied by an extensive sinusoidal vasculature with minimal extracellular matrix and a lining of fenestrated (sinusoidal) endothelial cells. Together these features allow for the efficient transport of nutrients to the highly metabolic hepatocytes. Strategies to incorporate vasculature into engineered constructs include the microfabrication of vascular units with accompanying surgical anastomosis during implantation (Griffith *et al.*, 1997; Kaihara *et al.*, 2000). For example, polymer molding using microetched silicon has been shown to generate extensive channel networks with capillary dimensions (Borenstein *et al.*, 2002). The incorporation of angiogenic factors within the implanted scaffolds has also been explored. Specifically, integration of cytokines important in angiogenesis, such as VEGF (Smith *et al.*, 2004), bFGF (H. Lee *et al.*, 2002), and VEGF in combination with PDGF (Richardson *et al.*, 2001), has been shown to promote the recruitment of host vasculature to implanted constructs. Furthermore, preimplantation of VEGF-releasing alginate scaffolds prior to hepatocyte seeding was demonstrated to enhance capillary density and to improve engraftment (Kedem *et al.*, 2005).

In addition to interactions with the vasculature, integration with other aspects of host tissue will constitute important future design parameters. For instance, incorporation

of hydrolytic or protease-sensitive domains into hepatocellular hydrogel constructs could enable the degradation of these systems following implantation. Of note, liver regeneration proceeds in conjunction with a distinctive array of remodeling processes, such as protease expression and extracellular matrix deposition. Interfacing with these features could provide a mechanism for the efficient integration of implantable constructs. Similar to whole-liver or cell transplantation, the host immune response following transplant of tissue-engineered constructs is also a major consideration. Immunosuppressive treatments will likely play an important role in initial therapies, although stem cell-based approaches hold the promise of implantable systems with autologous cells. Furthermore, harnessing the liver's unique ability to induce antigen-specific tolerance (Racanelli and Rehmann, 2006) could potentially represent another means for improving the acceptance of engineered grafts. Finally, incorporation of excretory functions associated with the biliary system will ultimately be required in future designs. Toward this end, current studies are focused on the development of *in vitro* models that exhibit biliary morphogenesis and recapitulate appropriate polarization and bile canaliculi organization (Auth *et al.*, 2001; Ishida *et al.*, 2001; Sudo *et al.*, 2005) as well as platforms for the engineering of artificial bile duct structures (Miyazawa *et al.*, 2005).

## VIII. ANIMAL MODELS

An essential element in the development of clinically relevant cell-based liver therapies of all types is the use of animal models in order to examine therapeutic effects as well as safety considerations. A wide range of large-animal models have been used to examine the effectiveness of extracorporeal support systems for liver failure (van de Kerkhove *et al.*, 2004). These systems can generally be divided into four major categories: partial hepatectomy, total hepatectomy, toxic, and ischemia models. Several important criteria are utilized in the development of animal models of fulminant hepatic failure. These include reproducibility, reversibility, liver failure-induced cell death, and a sufficient time interval for diagnosis and therapeutic intervention (Rahman and Hodgson, 2000). A recently proposed rat model exhibiting these criteria utilized a combinatorial approach; specifically, endotoxin treatment was performed in addition to 70% liver resection in order to produce an inflammatory component (Skawran *et al.*, 2003).

Animal models have also been used extensively to investigate liver regeneration. These can broadly be sepa-

rated into two categories: surgically induced and chemically induced (Palmes and Spiegel, 2004). Models in the chemical category include exposure to toxic doses of carbon tetrachloride or acetaminophen, both of which can induce localized centrilobular necrosis. Chemical-induced injury models are particularly useful for testing the efficacy of cell-based liver therapies, for these systems more closely mimic liver injuries commonly occurring in humans (i.e., drug toxicity). In the surgical category, the two-thirds partial hepatectomy model in the rat has been widely employed as a model in which the injury stimulus is well defined (Higgins and Anderson, 1931). Of note, parabiotic systems have demonstrated that after partial hepatectomy, factors regulating liver cell proliferation are present in the circulation (Fisher *et al.*, 1971; Moolten and Bucher, 1967). Consequently, although the hepatectomy model is less relevant clinically, it may serve as a well-controlled system to examine the importance of regenerative cues in the engraftment and proliferation of hepatic constructs implanted in extrahepatic sites. Extrahepatic implantation in subcutaneous or mesenteric sites is often utilized for tissue-engineered constructs due to the simplicity of access and improved imaging capabilities, although intrahepatic models that display relevant hepatotrophic stimuli continue to be explored. Overall, utilization of various animal models, both surgical and chemical, will likely be important in testing the effectiveness of cell-based liver therapies. Furthermore, knowledge of the mechanisms of liver injury and regeneration gained from these systems will provide an important foundation for the design of engineered liver tissue.

## IX. CONCLUSION

Although many challenges remain for the improvement of tissue-engineered liver therapies; substantial progress has been made toward a thorough understanding of the necessary components. The parallel development of highly functional *in vitro* systems as well as extracorporeal and implantable therapeutic devices is based on contributions from diverse disciplines, including regenerative medicine, developmental biology, transplant medicine, and bioengineering. In particular, novel technologies such as hydrogel chemistries, high-throughput platforms, and microfabrication techniques represent enabling tools for investigating the critical role of the microenvironment in liver function and, subsequently, the development of structurally complex and clinically effective engineered liver systems.

### I. INTRODUCTION

Hematopoietic stem cells (HSC) are characterized by their extensive self-renewal capacity and pluripotency. The probabilities of asymmetric versus symmetric division of HSC can be stochastically determined or influenced by external signals. There are many *in vitro* systems involving either bone marrow stromal support or provision of a combination of recombinant hematopoietic growth factors or both that can maintain HSC proliferation and differentiation over many weeks. However, the goal of significant expansion of the HSC population *in vitro* has proved more elusive. There has been an explosive increase in knowledge of the cellular and molecular bases of HSC regulation with the identification of pathways implicating Notch, Wnt, and Hedgehog as well as the cytokine signaling through the c-Kit, Flt3, IL-6-R, mpl, and Tie-2 receptors and downstream pathways involving Jak/STAT and homeobox proteins. There is considerable redundancy in pathways regulating HSC, and both additive and synergistic interactions between different pathways determine the balance between self-renewal and differentiation. With the identification of specific niches within the bone marrow, including endosteal and endothelial, it is now recognized that intimate interactions between HSC and regulatory components of the marrow microenvironment (osteoblasts, osteoclasts, granulocytes, mesenchymal cells, endothelium) determine HSC proliferative

status, pool size, differentiation, and mobilization. The migration of HSC between different niches and the vascular compartment is regulated by the chemotactic action of stromal-derived chemokine SDF-1 acting through its receptor CXCR4, in combination with CD44 and hyaluronic acid. The release of various proteases within the marrow environment leads to cleavage of stromal and HSC-associated adhesion molecules, receptors, cytokines, and chemokines, providing a further level of regulation.

### II. HISTORICAL BACKGROUND

For more than a century, the nature and developmental potential of stem cells within the hematopoietic system has been debated. The monophyletic hypothesis proposed that there was a single type of stem cell generating all myeloid and lymphoid lineage cells, whereas the polyphyletic hypothesis proposed a number of lineage-restricted stem cells. The prevailing view is a monophyletic one, with a pluripotent hematopoietic stem cell compartment and a hierarchy of progressively more lineage-restricted progenitor cells. The concept of a self-renewing, pluripotential hematopoietic stem cell (HSC) achieved experimental validation from the pioneering work of Till and McCulloch in the early 1960s using the spleen colony forming assay (CFU-s) in irradiated mice (reviewed in McCulloch and Till, 2005). They undertook a secondary passage of individually excised

spleen colonies and observed a high variability in the numbers of secondary colonies generated, which fitted a skewed (gamma) distribution. The probability that a single CFU-s on division would generate a new CFU-s (self-renewal) was calculated as 6, while production of a differentiated progenitor cell was 4. The conclusion was that this process was random, or stochastic. Other studies at this time indicated the existence of “hematopoietic inductive microenvironments” that influenced the differentiation of HSC. The relevance of stochastic processes versus external inductive signals in the regulation of HSC self-renewal and differentiation is still debated.

### III. PROPERTIES OF HEMATOPOIETIC STEM CELLS (HSC)

#### Asymmetric Division

HSC can divide either symmetrically or asymmetrically, depending on environmental, developmental, and stochastic factors (Fig. 49.1). Asymmetric division can be governed by intrinsic partitioning of regulators of cell fate (e.g., inhibition of Notch signaling by Numb and inhibition of Numb by Musashi) or by asymmetric exposure to extrinsic cues (reviewed in Ho, 2005). Symmetric divisions occur during hematopoietic expansion during development and in hema-

topoietic regeneration following myelodepletion or HSC transplantation. In the latter situations, well-documented data show HSC expansion in murine models. For example, after successive serial transfers of HSC in irradiated mice, a cumulative 8400-fold increase in HSC was observed (reviewed in Sauvageau *et al.*, 2004). Extensive expansion of human HSC was also observed following prolonged *in vitro* cultures of hematopoietic precursors from umbilical cord blood (Gammaitoni *et al.*, 2004). There is less evidence of symmetrical HSC division either *in vitro* or *in vivo* in adult humans (reviewed in Moore, 2005).

#### HSC Assays

*In vitro* or *in vivo* assays for HSC generally use a limiting-dilution strategy. Primitive, high-proliferative-potential progenitor (HPP-CFC) culture systems have been used as surrogate HSC assays (Muench *et al.*, 1993). More recent assays involve the development of cobblestone areas of phase-dark cells that develop beneath marrow stroma following two to three weeks (murine) or more than five weeks (human) coculture with bone marrow or CD34<sup>+</sup> cells (Jo *et al.*, 2000) (Fig. 49.2). These cobblestone area-forming cells (CAFC) have self-renewal and pluripotent differentiation potential. A modification of this assay involves quantitation of secondary progenitor erythroid and myeloid colony formation (CFC), e.g., after five weeks of stromal or cytokine-dependent culture (long-term culture-initiating cell assay-LTC-IC). The *in vivo* assays for murine HSC involve limiting dilution, competitive (e.g., with the addition of a genetically distinct marrow population) repopulation assay in irradiated recipients, with evaluation after three to six months. The immunodeficient SCID or NOD/SCID mouse supports human hematopoiesis following intravenous injection of  $2 \times 10^4$ – $2 \times 10^5$  CD34<sup>+</sup> cells and quantitation of engraftment by measure of human CD45<sup>+</sup> cells in the murine femoral bone marrow at five weeks and beyond can be used under limiting dilution conditions to quantify human HSC (SCID repopulating cells—SRC) (reviewed in Dick and Lapidot, 2005). Human HSC with long-term engraftment of NOD/SCID mice are in the CD38<sup>−</sup>, CD34<sup>+</sup> fraction (Ishikawa *et al.*, 2003). Mazurier *et al.* (2003) identified a new class of human HSC by direct intrafemoral injection in NOD-SCID mice—these were identified as CD34<sup>+</sup>, CD38<sup>low</sup>, CD36<sup>−</sup> subpopulations termed *rapid SCID repopulating cells* (R-SRCs), which rapidly generate high levels of human myeloid and erythroid regeneration within the injected femur, migrate to the blood, and colonize individual bone within two weeks after transplantation. While the presence of CD34 and the absence of CD38 provide reliable markers for human HSC, murine HSC are routinely isolated as cKit<sup>+</sup>, Sca-1<sup>+</sup>, lineage negative (Lin<sup>−</sup>) populations, with additional features such as Hoechst dye exclusion. CD34<sup>+</sup> is expressed on long-term repopulating HSC of the murine fetus and neonate but decreases with age so that HSC of 10-week-old mice are CD34<sup>−</sup> (Ogawa, 2002; Matsuoka *et al.*, 2001). The

**FIG. 49.1.** Model of HSC self-renewal and differentiation illustrating the role of key cytokines — Fit3 ligand (FL), cKit ligand (KL, also termed *stem cell factor* or Steel factor), thrombopoietin (Tpo), and Interleukin-6 (IL-6). The chemokine receptor CXCR4 and its ligand SDF-1 and the VEGF Receptor-1 (VEGFR-1) and its ligands are implicated in HSC migration and mobilization. The Notch, Wnt, and Indian Hedgehog (Ihh) signaling pathways have also been implicated in HSC self-renewal, as have the Polycomb group transcriptional repressor Bmi-1 and the HOX homeodomain protein HOXB4.

**FIG. 49.2.** A model illustrating the concept of the “late” cobblestone area-forming cell (CAFC) and its interaction with bone marrow stromal elements. SDF-1 produced by the marrow stroma establishes a gradient that attracts CXCR4<sup>+</sup> HSC that adhere via VLA-4-VCAM-1-mediated adhesion and then migrate beneath the stroma. Stromal membrane-associated cKit ligand (KL) and Flt3 ligand (FL) provide survival and proliferation signals to the HSC, while negative regulatory influences from the stroma (TGFβ, angiopoietin) override proliferative signals and place the HSC in a G0 state that persists for some weeks. Escape from quiescence may be a stochastic process or driven by an alteration in the balance between proliferation stimulating and inhibiting factors. At this stage the HSC proliferates and differentiates, forming colonies of 5–100 phase-dark cells by week 5. At this stage each cobblestone area contains on average of 1–4 HSC and 5–20 progenitors (CFU-GM, BFU-E).

observations clearly demonstrate that CD34 expression reflects the activation/kinetic state of HSC and that expression is reversible. In the murine system, the majority of HSC are CD38<sup>+</sup>, and there is a reciprocal relationship of CD34 and CD38 expression (Ogawa, 2002). Cell surface receptors of the SLAM family are differentially expressed among functionally distinct HSC, and progenitor populations of the mouse and HSC are CD150<sup>+</sup>, CD244<sup>+</sup>, and CD48<sup>+</sup>, while multipotent progenitors are CD244<sup>+</sup>, CD150<sup>+</sup>, and CD48<sup>+</sup> (Kiel *et al.*, 2005).

### HSC Numbers and Proliferative Status

It has been suggested that HSC numbers are conserved in mammals, with cats, mice, and rats having comparable numbers (~11,000–12,000) (Abkowitz *et al.*, 2002; McCarthy, 2003). If extrapolated to humans, the frequency of HSC would be 0.7–1.5/10<sup>8</sup> marrow cells, a frequency that is 20-fold less than estimated by the NOD/SCID repopulating assay. Measurements of granulocyte telomere length have been used to estimate human HSC kinetics, and results showed that replication is infrequent, on average once every 45 weeks, substantially slower than the average rates estimated for murine (once per 2.5 weeks) or cats (once per 8.3–10 weeks) (Shepherd *et al.*, 2004).

## IV. ONTOGENY OF HSC

In the avian and mammalian systems, the ontogeny of hematopoiesis involves a sequence of vascular migration streams of primitive hematopoietic stem and progenitor cells (hematogenous metastases), initiating from the earliest sites of HSC development and sequentially colonizing developing myeloid (fetal liver, spleen, bone marrow) and

primary lymphoid (thymus) organs (reviewed in Moore, 2006). In mammals, hematopoiesis is initiated in the blood islands of the yolk sac, where both primitive and definitive lineage hematopoietic precursors arise. Intraembryonic hematopoiesis is subsequently initiated in the aorta-gonad-mesonephros (AGM) region in or near the endothelium of the dorsal aorta, where HSC capable of repopulating adult animals arise (Moore, 2006). Bertrand *et al.* (2005) identified a population of CD45<sup>ve</sup>, c-Kit<sup>+</sup>, CD31<sup>+</sup>, HSC arising in the AGM region in the splanchnic mesoderm underlying aortic endothelial cells, within GATA-3<sup>+</sup>, CD31<sup>+</sup> cell clusters, and these cells did not colocalize with aortic endothelium as previously thought. The onset of definitive (adult engraftment potential) HSC activity in the AGM region was paralleled by that in the placenta starting in the mouse at E10.5–11.0 days of gestation (Gekas *et al.*, 2005). There remains considerable debate as to the role of yolk sac hematopoiesis in lymphohematopoietic development. One view is that the yolk sac is a transient source of primitive hematopoietic progenitors, whereas definitive, pluripotent HSC arise exclusively within the AGM region. Alternatively, and more plausible, is the view that HSC arise independently in the AGM and yolk sac and migrate to the fetal liver and thymus — organs that become major developmental sites of hematopoiesis and lymphopoiesis (Moore, 2006). The subsequent migration of HSC from the fetal liver to bone marrow provides an opportunity for harvesting HSC from the circulation. The umbilical cord blood population is a rich source of HSC and has been used as an HSC transplant source in a wide range of hematological and oncologic disorders (reviewed in Broxmeyer, 2005).

## V. MIGRATION, MOBILIZATION, AND HOMING OF HSC

### Bone Marrow (BM) Homing of HSC

Large numbers of HSC move into and out of the circulation on a daily basis. Homing of HSC to the BM is rapid (hours), involving cells traversing across the BM sinusoidal endothelium, which presents adhesion molecules and chemokines facilitating the process (reviewed in Lapidot *et al.*, 2005). The seeding efficiency of HSC to the BM, as determined by secondary passaging, has generally been accepted as 10–20% by 24 h. However, Benveniste *et al.* (2003), using competitive repopulation and tracking of a single purified HSC in mice, concluded that HSC engraft with near-absolute efficiency. This view has recently been challenged, since individual HSC (SP cells) were only able to reconstitute up to 35% of mice (Camargo *et al.*, 2006). The transition from quiescence to active cell cycling of HSC was associated with significant loss of engraftment potential (Glimm *et al.*, 2000), which was not associated with loss of expression of the integrins VLA-4, VLA-5 or the chemokine receptor CXCR4.

### Role of the SDF-1/CXCR4 Chemokine Pathway in HSC Homing and Migration

The chemokine SDF-1 is expressed on bone marrow vascular endothelium, immature osteoblasts in the endosteal region, and marrow stromal cells, while its receptor, CXCR4, is expressed on HSC and progenitors (Figs. 49.2 and 49.3). The SDF-1/CXCR4 pathway plays a major role in regulating the mobilization, migration, and retention of HSC (reviewed in Lapidot *et al.*, 2005). This chemokine pathway is essential for HSC seeding from the fetal liver to the bone marrow during development; however, CXCR4-deficient HSC can, with reduced efficiency, engraft adult irradiated mice (reviewed in Moore, 2006). Elevation of plasma levels of SDF-1 occurs following intravenous injection of an adenovector expressing SDF-1, and the consequent reversal of the SDF-1 gradient from blood to marrow leads to mobilization of HSC and progenitors (Hattori *et al.*, 2001). Overexpression of CXCR4 on human CD34<sup>+</sup> cells by gene transfer increased their proliferation, migration, and NOD/SCID engraftment potential (Lapidot *et al.*, 2005). CXCR4 neutralization abolished human intravenous or intrafemoral CD34<sup>+</sup> engraftment in NOD/SCID mice, indicating the essential role of this receptor in BM seeding and colonization as well as in homing (Lapidot *et al.*, 2005).

The adhesion receptor CD44 and its major ligand, hyaluronic acid, are essential for HSC homing to marrow and spleen. HSC express CD44 and migrate on hyaluronic acid toward a gradient of SDF-1, acquiring a polarized morphology with CD44 concentrated at the leading edge of pseudopodia (Avigdor *et al.*, 2004). Since hyaluronic acid is expressed on both BM endothelium and endosteum, it is likely that

**FIG. 49.3.** Model illustrating HSC adherence to bone marrow stromal cells via VLA4 binding to VCAM-1 and cKit-binding transmembrane cKit ligand (KL-1). SDF-1 produced by the stroma induces matrix metalloproteinase-9 (MMP9) production by HSC and macrophages, and this in turn cleaves the transmembrane KL-1, releasing soluble active ligand (sKL). The HSC-mobilizing role of G-CSF is explained in part by increased numbers and activation of neutrophils within the bone marrow, with secretion of a number of proteases (elastase, cathepsin G) that cleave VCAM-1 and untether HSC. Protease activity is also implicated in the cleavage and inactivation of SDF-1. HSC express the membrane-bound ectopeptidase CD26, which removes dipeptides from the amino-terminus of proteins and acts as a negative regulator of the SDF-1-CXCR4 axis.

CD44 plays a key role in SDF-1, mediated transendothelial migration, and localization in specific BM niches.

### HSC Mobilization

Beginning in the mid-1980s, autologous peripheral blood was used for transplantation, particularly blood obtained after chemotherapy at the rebound in hematopoietic regeneration. The availability of two hematopoietic growth factors, G-CSF and GM-CSF, in recombinant form led to their use as HSC- and progenitor-mobilizing agents. G-CSF treatment for mobilization of HSC, peaking at five to six days, is currently the most efficient strategy for clinical HSC collection. A number of chemokines (IL-8, MCP-1, MIP-1 $\alpha$ , Gro $\beta$ , SDF-1) also induce rapid HSC mobilization in murine models, with peak HSC and progenitor mobilization in a few hours, in contrast to the days required with CSFs. Movement of HSC between endosteal, perivascular, and intravascular sites is influenced by G-CSF activation of marrow neutrophils, with resulting protease release and cleavage and inactivation of SDF-1 (Fig. 49.3). One mechanism proposed to explain the ability of G-CSF treatment to mobilize HSC involves a reported reduction in SDF-1<sup>+</sup> possibly due to degradation by neutrophil protease activity and an increase in its receptor CXCR4 in the bone marrow, whereas their protein expression in blood was less affected (Petit *et al.*, 2002). Activated neutrophils release matrix metalloproteinase-9 (MMP-9) and lactoferrin from specific granules and neutrophil elastase, cathepsin G, and proteinase 3 from azurophilic granules (Fig. 49.3) (reviewed in Papayannopoulou, 2004). The release of multiple proteases within the BM can lead to cleavage or degradation of vascular cell adhesion molecule-1 (VCAM-1), membrane-bound cKit ligand (KL), SDF-1, and its receptor CXCR4 — all events that can untether HSC from their niches and facilitate their proliferation, differentiation, and mobilization (Fig. 49.3) (Heissig *et al.*, 2002). Studies in genetic models of protease deficiency, including models with multiple protease deficiencies, surprisingly did not show impaired G-CSF-induced HSC mobilization (Papayannopoulou, 2004). Thus, the contribution of a single protease to mobilization may not be critical, but multiple proteases acting in a cell context-specific manner appear important. Targeting and reduction of SDF-1 or its receptor may be common denominators of proteases implicated in HSC mobilization. HSC express the membrane-bound ectopeptidase CD26, which removes dipeptides from the amino-terminus of proteins, and CD26 null mice have an attenuated response to G-CSF. CD26 expression on HSC negatively regulated their homing and engraftment, and by inhibiting or deleting CD26 it was possible to increase greatly the efficiency of engraftment (Christopherson *et al.*, 2004). CD26 expression may regulate HSC engraftment potential by inactivating SDF-1 produced by marrow stroma. CXCR4 antagonists such as AMD3100 have also been shown to be effective in mobilized HSC with long-term repopulating capacity in nonhuman primates (Laro-

chelle *et al.*, 2006). Signals from the sympathetic nervous system also regulate HSC egress from bone marrow (Katayama *et al.*, 2006). Pharmacologic or genetic ablation of adrenergic neurotransmission resulted in the failure of HSC and progenitors to egress the marrow following G-CSF stimulation, while a  $\beta$ 2 adrenergic agonist enhanced HSC mobilization in both control and norepinephrine-deficient mice. Kollet *et al.* (2006) have linked bone remodeling with regulation of stress-induced mobilization of HSC and progenitor cells. They showed that an increase in osteoclast numbers is associated with mobilization. RANK ligand (RANKL) is a member of the TNF family of cytokines, which is necessary for the production of osteoclasts, is a product of osteoblasts, and is responsible for the balance between bone production and destruction in skeletal remodeling. RANKL altered osteoclast expression of MMP-9 and cathepsin K, which cleave membrane-bound KL, resulting in decreased osteoblast KL and the production of osteopontin. Inhibition of osteoclasts with calcitonin reduced G-CSF stem/progenitor mobilization. Mice deficient in the protein tyrosine phosphatase- $\epsilon$  (PTP- $\epsilon$ ) have dysfunctional osteoclasts, and HSC in these mice did not mobilize on treatment with either RANKL or G-CSF (Kollet *et al.*, 2006).

The Rho guanosine triphosphatases, Rac1 and Rac2, play distinct roles in actin organization, hematopoietic cell survival, and proliferation. Deletion of both Rac1 and Rac2 murine alleles led to a massive egress of HSC from the marrow to blood, and Rac1<sup>-/-</sup> mice showed profound defects in engraftable HSC (Gu *et al.*, 2003). Rac2-deficient HSC showed defective adhesion, motility, and interaction with the hematopoietic microenvironment and had a significant competitive repopulation defect (Jansen *et al.*, 2005).

## VI. HSC PROLIFERATION AND EXPANSION *IN VITRO*

The *in vitro* maintenance and potential expansion of HSC has been the subject of extensive investigation since the mid-1970s, beginning with murine long-term bone marrow cocultures with murine bone marrow stroma (Dexter cultures) and subsequent adaptation of this system to humans, using both human and murine stroma. With the discovery of a number of hematopoietic growth factors (interleukins, colony stimulating factors) and their availability as recombinant proteins, *in vitro* culture systems were developed that supported extensive cell and progenitor expansion in the absence of stroma but in the presence of combinations of cytokines (Moore, 2005).

### Stromal-Based Cultures

Dexter and colleagues first introduced *in vitro* culture systems for long-term growth of murine BM on preestablished marrow stroma. Similar systems, but with the addition of corticosteroids, were developed for human (Moore *et al.*, 1980) and primate BM (Moore *et al.*, 1979). With adult

human LTBM, hematopoiesis was generally limited to five to eight weeks, and there was continuing decay in repopulating HSC and progenitors over time. A number of modifications to the long-term stromal coculture system have been developed to prevent the decrease in stem and progenitor output, for example, the use of different sources of stroma, including human vascular endothelium, human fetal spleen, and stroma from different species, including mouse, primate, and pig. Frequent readdition of fresh media and cytokines, ranging from one exchange per week up to total daily feeding, resulted in increased CFC and LTC-IC output and led to the development of clinical scale flat-plate perfusion bioreactors (Koller *et al.*, 1993). Unfortunately, the use of media exchange alone has not translated into expansion of repopulating HSC. Cord blood CD34<sup>+</sup> cells have been expanded in transwell culture systems (noncontact cultures) above AFT024 mouse fetal liver stromal cells with additional cytokines (Flt3 ligand [FL], KL, thrombopoietin [Tpo], IL7) (Lewis *et al.*, 2001). In stromal-supported cultures of cord blood, CD34<sup>+</sup> cells and cytokine- (FL, Tpo, KL +/IL6) enhanced production of CAFC (11–89-fold over six weeks) was noted, while NOD/SCID repopulating cells increased 10–14-fold by two weeks but were absent by week 5 (Kusadasi *et al.*, 2001). Expanded cells engrafted primary and secondary NOD/SCID mice, and day 7–expanded cells engrafted primary, secondary, and tertiary fetal sheep. The murine OP9 stromal cell line derived from osteopetrotic op/op mice has been used to support long-term murine hematopoiesis in the absence of added cytokines; however, it is not supportive of human CD34<sup>+</sup> cells. The addition of Tpo to the stromal coculture system or transduction of OP9 with an adenovector expressing Tpo permitted very efficient long-term (16+ weeks) human hematopoiesis initiated with cord blood CD34<sup>+</sup> cells, with sustained generation and extensive cumulative expansion of LTC-IC (Gammaitoni *et al.*, 2004). In a comparable system of coculture of OP9 transduced with adenovectors expressing Tpo, KL, and FL but using adult bone marrow or G-CSF-mobilized blood CD34<sup>+</sup> cells, hematopoiesis was sustained for 12 weeks, but a much lesser degree of LTC-IC expansion was noted (three- to fourfold) (Feugier *et al.*, 2005). In the latter system, addition of human (but not murine) M-CSF or CD14<sup>+</sup> monocyte/macrophages to the cultures substantially decreased progenitor and HSC expansion, indicating that accumulation of differentiated cells, particularly macrophages, exerted a negative influence on HSC proliferation.

### Cytokine-Supplemented Cultures

It was found that direct contact between stromal cells and hematopoietic cells was not necessary for long-term *in vitro* hematopoiesis (Lewis *et al.*, 2001), and hematopoiesis could be maintained in cultures fed with media conditioned by stromal feeders. This information suggested the feasibility of using stromal-free cytokine-supplemented cultures for expanding HSC and progenitors *in vitro*. Over the years,

the use of phenotypic and functional assays has identified a number of cytokines that have distinct stimulatory effects on primitive hematopoietic cells, particularly when used in various combinations (Fig. 49.1). These include FL, KL, Tpo, IL-1, IL-3, IL-6, IL-11, IL-12, G-CSF, and GM-CSF (Haylock *et al.*, 1992; Muench *et al.*, 1993; reviewed in Moore, 2005). Using limiting-dilution assays for competitive repopulating cells, modest degrees of HSC expansion have been reported in murine *in vitro* expansion systems using combinations of KL, FL, and IL-11. Optimal growth factor combinations are required to achieve *in vitro* HSC expansion, and while KL and FL are sufficient to maintain survival and proliferation, retention of HSC function requires activation of additional pathways, for example, gp130, stimulated via IL-6 or IL-11 (reviewed in Sauvageau *et al.*, 2004). Haylock *et al.* (1992) were the first to report a CFC expansion of 66-fold in human CD34<sup>+</sup> cultures stimulated with IL-1, IL-3, IL-6, G-CSF, and GM-CSF. Subsequent studies showed the importance of specific cytokines for the expansion of defined progenitor cell types. In a human CD34<sup>+</sup> expansion system, IL-6 plus soluble IL-6 receptor (to maximize IL-6 signaling where IL-6 receptor density could be limiting), together with FL, KL, and Tpo, resulted in an approximate fourfold expansion of HSC, as determined by NOD/SCID limiting-dilution repopulation (Ueda *et al.*, 2000). Both FL and IL-6/sIL-6 are important for expanding cord blood CD34<sup>+</sup>-derived LTC-IC, while the addition of KL to either of these factors enhances generation of CFC (Zandstra *et al.*, 1998). In contrast, FL, KL, and IL-3 most efficiently stimulated BM LTC-IC proliferation, whereas the addition of IL-6/sIL-6R or Tpo to this combination was required for expansion of CFC (Zandstra *et al.*, 1998). Regardless of the cytokine combination used, rigorous limiting-dilution engraftment studies in NOD/SCID mice have, in the majority of studies, shown that in cytokine-supplemented cultures there was generally a loss, maintenance, or modest (two- or fourfold) expansion of human SRC (Ueda *et al.*, 2000). In contrast, Piacibello *et al.* (1999) (Gammaitoni *et al.*, 2004; reviewed in Moore, 2005) reported a major expansion of LTC-IC and progenitors (3000-fold) and a 70-fold expansion of NOD/SCID engrafting HSC (SRC) in cultures of CB CD34<sup>+</sup> cells with FL, KL, Tpo, and IL-6. Under similar conditions but with CD34<sup>+</sup> cells from adult BM and mobilized peripheral blood (MPB), *ex vivo* expansion was shorter in duration and extent, with SRC expansion of only sixfold by three weeks (Gammaitoni *et al.*, 2004). In a modified stromal-free culture system with cord blood-derived CD34<sup>+</sup> cells and a cocktail of four cytokines (KL, FL, Tpo, and IL-6), with CD34<sup>+</sup> re-isolation at monthly intervals, continuous expansion of HSC was observed over 16–20 weeks by *in vitro* CAFC and LTC-IC assays and by NOD/SCID engraftment and secondary and tertiary passaging (Gammaitoni *et al.*, 2004) (Table 49.1). Despite extensive proliferation, the telomere length of cultured hematopoietic cells initially increased, and it was only at late stages of culture that telomere shortening was detected. Telomere

Modified from Gammaitoni *et al.* (2004).

length stabilization correlated with high telomerase levels (Table 49.1). In contrast, cytokine-stimulated adult CD34<sup>+</sup> cells from bone marrow or G-CSF–mobilized blood showed CD34<sup>+</sup> and NOD/SCID engraftment expansions of sixfold for only three to four weeks, with telomere shortening and low levels of telomerase activity. Human fetal liver–derived HSC with NOD/SCID repopulating capacity have been expanded 10- to 100-fold net expansion over 28 days of culture with FL, Tpo, KL, and IL-6 and 8% human AB plasma (Rollini *et al.*, 2004). The CD133<sup>+</sup> G0 cell subpopulation from cord blood is enriched for HSC and progenitors (CFC), with an LTC-IC incidence of 1 in 4.2 cells and a CFC incidence of 1 : 2.8 cells (Summers *et al.*, 2004). These cells could be expanded with cytokines in a serum-free, stromal-free culture system for up to 30 weeks, resulting in a 100-million-fold amplification of progenitors. Quantitation of HSC expansion *in vitro* is complicated by divergence in results when *in vitro* HSC assays (CAFC, LTC-IC) are used as an endpoint, versus *in vivo* (SCR). While this has led to considerable debate as to the validity of the assays, the issue is probably related to the efficiency of the respective systems. Clearly, the *in vivo* assay requires HSC survival and homing to the HSC niches of the mouse bone marrow, and there is evidence that *in vitro* culture or cycling HSC may be less efficient *in vivo* while retaining potential to self-renew and form CAFC/LTC-IC *in vitro*. In this context, Liu *et al.* (2003) cultured CB CD34<sup>+</sup> cells for up to five days with a cocktail of cytokines, labeled the cells with 111-indium, and deter-

mined recovery at 48 h following intravenous injection into NOD/SCID mice. Cultured, cycling HSC and progenitors showed a reduction of marrow homing (from 11.3% to 5.4%), with reduced homing to spleen, liver, and lung. Acute cytokine deprivation in the *in vivo* environment and Fas/CD95-mediated cell death may be responsible for the reduced engraftment efficiency of cultured HSC.

### Morphogens and HSC Regulation

In addition to the classic hematopoietic growth factors, signaling pathways implicated in general development have also been shown in various models to influence HSC proliferation and differentiation (Fig. 49.1).

#### Notch

In differential gene display, Notch1 has consistently been shown to characterize the murine and human HSC. Notch1-null mouse embryos showed defective hematopoietic (and vascular) development and were devoid of HSC. Retrovirus-mediated expression of activated Notch1 enhanced HSC self-renewal, and a similar effect of differentiation inhibition and progenitor/HSC expansion was reported with activated Notch4 (Int3) (Ye *et al.*, 2003). The Bernstein group (Varnum-Finney *et al.*, 2003; Delaney *et al.*, 2005) showed that incubation of murine BM precursors with the Notch ligand Delta1 extracellular domain fused to the Fc portion of human IgG1, together with cytokines (KL, IL-6, IL-11, and Flt3L), inhibited myeloid differentiation and

promoted several log increases in precursors capable of short-term lymphoid and myeloid repopulation. Addition of IL-7 promoted T-lymphocyte development, whereas GM-CSF induced myeloid differentiation. It has been shown that Notch signaling mediated by both Delta and Jagged ligands expands the HSC compartment while blocking or delaying terminal myeloid differentiation. The quantitative aspects of Notch signaling in determining hematopoietic precursor fate has been demonstrated by Delaney *et al.* (2005), who showed in CD34<sup>+</sup> cord blood cultures that low densities of the Notch ligand Delta1 enhanced *in vitro* generation of CD34<sup>+</sup> cells as well as CD14 and CD7 cells, consistent with myeloid and lymphoid differentiation, whereas higher concentrations induced apoptosis of CD34<sup>+</sup> cells but not CD7 T-cell precursors. A role for combinatorial effects of Jagged stimulation of Notch and cytokine-induced signaling pathways (Kit, Flt3, Mpl) was reported in murine HSC cultures, with a 10- to 20-fold expansion of HSC with long-term repopulating potential (Kertesz *et al.*, 2006). Inhibition of Notch signaling leads to accelerated differentiation of HSC *in vitro* and depletion of HSC *in vivo* (Duncan *et al.*, 2005). However, using a Cre-LoxP-mediated inactivation system, mice with simultaneous inactivation of Jagged and Notch1 survived normally, even following chemotherapy-induced myelosuppression (Mancini *et al.*, 2005). HSC regulation is complex, cell-context dependent, and plagued by potential compensation systems, and while the study excludes an essential role for Jagged1 and Notch1 during hematopoiesis, there are four Notch receptors and five ligands, and the Notch pathway cross-talks with the Wnt pathway, with more than nine frizzled receptors and 12 ligands (Duncan *et al.*, 2005). The *Drosophila* hairy and enhancer of split (HES) 1 basic helix-loop-helix protein is a major downstream effector of the Notch pathway and is expressed at high levels in HSC-enriched CD34<sup>+</sup>, CD38<sup>-</sup> subpopulations. Conditional expression of HES1 in murine and human HSC inhibited cell cycling *in vitro* and cell expansion *in vivo*, with preservation of long-term reconstituting function.

## Wnt

The Wnt pathway has been implicated in HSC proliferation (reviewed in Reya and Cleavers, 2005). Notch signaling was required for Wnt-mediated maintenance of undifferentiated HSC but not for their survival or entry into cell cycle (Duncan *et al.*, 2005). Wnt signaling represses glycogen synthase kinase-3 $\beta$  (GSK3 $\beta$ ), leading to accumulation of  $\beta$ -integrin but also accumulation of intracellular fragments of Notch and activation of Notch target genes, such as Hes1. Hematopoietic repopulation by mouse or human stem cells has been augmented by administration of a GSK-3 inhibitor to recipient mice (Trowbridge *et al.*, 2006). The inhibitor improved neutrophil and megakaryocyte recovery and mouse survival and enhanced sustained long-term repopulation. The GSK-3 inhibitors modulated gene targets of Wnt, hedgehog, and Notch pathways in primitive hematopoietic

cells, without affecting mature cells. Wnt-5A injected *in vivo* into immunodeficient mice enhanced engraftment by human CD34<sup>+</sup> cells (Murdoch *et al.*, 2003). Reya *et al.* (2003) showed that overexpression of activated  $\beta$ -catenin expanded the pool of HSC in long-term culture. Activation of Wnt signaling in HSC increases expression of HOXB4 and Notch1, both implicated in HSC self-renewal. Ectopic expression of axin or the frizzled ligand-binding domain, both inhibitors of the Wnt signaling pathway, inhibited HSC growth *in vitro* and reduced *in vivo* engraftment. Wnt3a-palmitoylated protein has been purified and shown to induce self-renewal of HSC (Willert *et al.*, 2003). The essential role of  $\beta$ -catenin in hematopoiesis has been questioned in studies of mice with Cre-loxP-mediated inactivation of  $\beta$ -catenin, since there was no impaired HSC ability to self-renew and differentiate (Cobas *et al.*, 2004).

## Hedgehog

Sonic hedgehog (SHH) treatment in CD34<sup>+</sup> cultures induced expansion of human HSC, and Noggin, a specific inhibitor of bone morphogenetic protein-4 (BMP-4), inhibited SHH-induced proliferation, indicating that SHH regulates HSC via mechanisms that are dependent on downstream BMP signals (Bhardwaj *et al.*, 2001). Ihh-expressing human stromal cells supported CD34<sup>+</sup> cells, with markedly enhanced production of progenitor CFC above the stroma but no change in long-term cobblestone formation (Kobune *et al.*, 2004).

## Bone Morphogenic Protein

CD34<sup>+</sup>, CD38<sup>-</sup> HSC express the bone morphogenic protein type 1 (BMP-1) receptors activin-like kinase (ALK-3 and ALK-6) and their downstream transducers SMAD-1, -4, and -5. Like TGF $\beta$ , high concentrations of BMP-2, -4, and -7 inhibited HSC proliferation but maintained their long-term survival and repopulating potential, whereas low concentrations of BMP-4 induced HSC proliferation and differentiation (Bhatia *et al.*, 1999).

## Molecular Pathways Implicated in HSC Self-Renewal

### Jak-STAT

Transduction of mouse HSC with constitutively activated STAT3 enhanced HSC self-renewal under stimulated but not homeostatic conditions, while a dominant negative form of STAT3 suppressed self-renewal (Chung *et al.*, 2006). The STAT5 pathway is activated strongly following ligand binding to the erythropoietin and IL-3 receptors and weakly following FL binding to Flt3. However, constitutively activating mutants of Flt3, found in ~25% of human acute myeloid leukemia, are associated with strong activation of STAT5 (reviewed in Moore, 2005). A constitutively activated double mutant of STAT5a [STAT5a(I\*6)] transduced into CD34<sup>+</sup> cells promoted enhanced HSC self-renewal, as measured by

CAFC assay, and promoted enhanced erythroid differentiation relative to myeloid (Schuringa *et al.*, 2004). This was causally linked to down-regulation of C/EBP $\alpha$ , a transcription factor uniquely associated with granulocytic differentiation.

### Bmi-1

The Polycomb-group transcriptional repressor gene Bmi-1 has been implicated in HSC maintenance, and loss-of-function studies showed profound defects in HSC (Park *et al.*, 2003). Bmi-1 overexpression down-regulated expression of p16 and p19Arf, which are encoded by ink4a, and enhanced HSC symmetrical division, resulting in expansion of multipotent progenitors *in vitro* and enhanced HSC repopulation *in vivo* (Jacobs *et al.*, 1999).

### The HOX Family of Hematopoietic Regulators

The HOX homeodomain (HD) proteins are DNA-binding transcription factors that have long been recognized as key regulators of development and hematopoiesis. *HOX* genes are expressed at various stages during hematopoietic development. Mounting evidence suggests that *HOXA9* plays important roles in normal hematopoiesis. Targeted disruption of *HOXA9* in mice severely reduces the number of HSC and progenitor cells, while enforced expression of *HOXA9* promotes proliferative expansion of HSC and progenitor cells and subsequently inhibits their differentiation (reviewed in Sauvageau *et al.*, 2004; Moore, 2005). These data highlight the importance of precise control of *HOXA9* protein levels during hematopoiesis. *HOXB4* plays a critical role in promoting HSC self-renewal and engraftment (reviewed in Sauvageau *et al.*, 2004; Moore, 2005). Combinations of early-acting cytokines increased *HOXB4* promoter activity in primitive hematopoietic cells, and Tpo acting via Mpl and p38MAPK increased *HoxB4* expression two- to threefold in primitive hematopoietic cells (Kirito *et al.*, 2003). In Tpo<sup>-/-</sup> mice, hematopoietic *HoxB4* expression was two- to fivefold lower than in wild-type animals (Kirito *et al.*, 2003). Wnt signaling in primitive hematopoietic cells also induces *HOXB4* expression (Reya *et al.*, 2003). *HOXB4*-null mice had reduced HSC and progenitor cells, due to impaired proliferative capacity, but did not show perturbed lineage commitment. Retroviral-mediated ectopic expression of *HOXB4* resulted in a rapid increase in proliferation of murine HSC both *in vivo* (1000-fold increase in transduced HSC in a murine transplant model) and *in vitro* (40-fold expansion of murine HSC), with retention of lymphomyeloid repopulating potential and enhanced regenerative capability in mice (reviewed in Sauvageau *et al.*, 2004). However, high levels of *HOXB4* expression in human umbilical cord blood (CB) CD34<sup>+</sup> cells were recently reported either to increase proliferation of HSC and inhibit differentiation (Schiedlmeier *et al.*, 2003) or to direct the cells toward a myeloid differentiation program rather than increasing proliferation (Brun *et al.*, 2003). These studies suggest that

in human hematopoietic progenitors, *HOXB4* affects cell fate decisions (self-renewal, differentiation, or a differentiation block) in a concentration-dependent manner. Therefore, like *HOXA9*, the relative abundance of *HOXB4* requires precise regulation. Molecular mechanisms and target genes responsible for *HOXB4*-induced HSC expansion remain to be elucidated. Overexpression of *HOXB4* point mutations lacking the capacity to bind DNA (*HOXB4*(N<sup>51</sup>→A) failed to enhance proliferative activity of transduced BM populations, whereas mutants that blocked the capacity of HOX to cooperate with the transcription factor PBX in DNA-binding *HOXB4* (W→G) conferred a pronounced proliferative advantage *in vitro* and *in vivo* to transduced BM populations (Beslu *et al.*, 2004). This mutant was comparable to wild-type *HOXB4*, in that its elevated level promoted a comparable degree of HSC expansion. This was distinct from results obtained by knocking down the expression of PBX in *HOXB4*-overexpressing BM cells using lentivector transduction with a PBX antisense construct. In this system the HSC were more than 20 times more competitive than HSC overexpressing *HOXB4* with PBX levels intact, which were, in turn, 20–50 times more competitive than wild-type BM (Krosl *et al.*, 2003). The likely explanation for these observations is that *HOXB4* and PBX genes act on distinct pathways in the HSC, the former promoting self-renewal and the latter inhibiting it. A developmentally important mechanism for regulating HOX gene expression was identified by Davidson *et al.* (2003). *Cdx4* belongs to the caudal family of homeobox genes, which have been implicated in anteroposterior patterning of the axial skeleton and regulation of Hox gene expression. A *Cxc4* mutation in zebra fish causes severe anemia, with complete absence of Runx1 in blood cells (Davidson *et al.*, 2003). Injection of mutants with *Hoxb7a* and *Hox9a* mRNA almost completely rescued *Cdx4* mutants. Retroviral transduction of mouse ES-derived embryoid body cells with *Cdx4* increased expression of *HoxB4* (×30), *HoxB3* (19×), *HoxB8* (5×), and *Hoxa9* (4×) — all implicated in HSC or progenitor expansion. And *Cxc4* was more potent than *HoxB4* in stimulating hematopoiesis and CFU-GEMM production (Davidson *et al.*, 2003).

The abundance of a given cellular protein is regulated by the interplay between its biosynthesis and degradation. During normal hematopoietic development, *HOXA9* is strongly expressed in the CD34<sup>+</sup> populations enriched in early myeloid progenitors and is turned off when cells exit the CD34<sup>+</sup> compartment and undergo terminal differentiation. In conjunction with decreased biosynthesis, rapid turnover of *HOXA9* would ensure low steady-state levels, which are necessary for proper execution of differentiation into myeloid lineages. *HOXB4* is also expressed at high levels in HSC/progenitor compartments and is down-regulated but maintains low-level expression during differentiation. The studies of the biochemical mechanisms controlling the activities of *HOXA9* and *HOXB4* thus far have been focused primarily on transcriptional regulation. Little is

known about how their cellular abundance is controlled at the posttranslational level. Identification of proteins involved in the removal of HOXA9 and HOXB4 will be necessary for understanding the elaborate regulatory circuitry governing hematopoiesis. Posttranslational regulation of HOX protein levels has been linked to their ubiquitin-dependent proteolysis by the CUL-4A ubiquitin-ligase (Y. Zhang *et al.*, 2003).

Some transcription factors travel between cells because they contain protein domains that allow them to do so. This is the case for the HIV transcription factor TAT and for several homeoproteins, such as Engrailed, HOXA5, HOXB4, HOXC8, EMX1, OTX2, and PAX6. Direct paracrine homeoprotein activity has not been considered, yet in theory it would represent a way for neighboring hematopoietic cells to exchange proliferative and differentiative signals. Bone marrow stromal cells (murine MS-5 stroma) have been lentivector transduced with a vector expressing HOXB4 linked to an immunoglobulin kappa chain leader sequence (signal peptide), which is cleaved during protein secretion. Coculture of human CB CD34<sup>+</sup> cells on this stroma resulted in a two- to threefold greater expansion of cells and progenitors (CFC), a four- to tenfold greater expansion of LTC-IC, and a 2.5-fold expansion of NOD/SCID repopulating cells relative to control over five weeks of culture (Amsellem *et al.*, 2003). A biologically active TAT–HOXB4 fusion protein has been produced and expressed as a recombinant protein that on purification could be added to murine HSC cultures (Sauvageau *et al.*, 2004). Since the half-life of intracellular HOXB4 was ~1 h, TAT–HOXB4 was added to cell culture every 3 h for four days together with cytokines (KL, IL-6, IL-3), resulting in a five- to sixfold expansion of HSC, as measured by competitive repopulation.

Ectopic overexpression of HOXB4 in murine bone marrow produced HSC that were ~40-fold more competitive than untransduced cells in mouse repopulation assay, and by three to five months the HSC pool size of reconstituted mice equaled, but never exceeded, that of untreated control mice (Sauvageau *et al.*, 2004). High-level ectopic expression of HOXB4 in human cord blood CD34<sup>+</sup> cells had a selective growth advantage in NOD/SCID mice but with substantial impairment in myeloerythroid differentiation and B-cell development (Shojaei *et al.*, 2005). In nonhuman primate competitive repopulating transplantation models, HOXB4-overexpressing CD34<sup>+</sup> cells had a 56-fold higher short-term, and fivefold higher long-term (6 mo) engraftment than control cells (X. Zhang *et al.*, 2006).

## VII. NEGATIVE REGULATION OF HSC

TGF $\beta$  maintains HSC in a quiescent or slowly cycling state, and this cell-cycle arrest was linked to up-regulation of the cyclin-dependent kinase inhibitor p57KIP2 in primary human hematopoietic cells (Fig. 49.2) (Scandura *et al.*, 2004). Fortunel *et al.* (2003) attributed the TGF $\beta$  affect in

part to down-modulation of cell surface expression of tyrosine kinase receptors cKit, Flt3, and IL-6R and the Tpo receptor Mpl. This negative regulatory role of TGF $\beta$  has been challenged by Larsson *et al.* (2003), who showed that TGF $\beta$ -R1-null mice had normal *in vivo* hematopoiesis and a normal HSC cell-cycle distribution and did not differ in long-term HSC repopulating potential as compared to wild-type animals. The negative regulatory role of angiopoietin and osteopontin is discussed in the following section in the context of quiescence of HSC in osteoblast niches.

Two cyclin-dependent kinase inhibitors (CKI), p21 (Cip1/Waf1) and p27kip1, have been shown to govern the pool size of HSC and progenitors, respectively (Cheng and Scadden, 2002). Enforced expression of the HOXB4 transcription factor and down-regulation of p21 (Cip1/Waf) can each independently increase murine HSC proliferation (Miyake *et al.*, 2006). When p21 knockdown and HOXB4 overexpression were combined in HSC, long-term competitive repopulating cells expanded 100-fold in five days, compared to wild-type HSC, and threefold greater than HOXB4 alone. The transcription factor MEF (or EL4F) regulates quiescence of primitive hematopoietic cells (Lacorazza *et al.*, 2006). MEF-null HSC display increased residence in G0, with reduced 5-bromodeoxyuridine incorporation *in vivo* and impaired cytokine proliferation *in vitro*. MEF-null mice are consequently relatively resistant to the myelosuppressive effects of chemotherapy or radiation.

## VIII. HEMATOPOIETIC STEM CELL NICHES

Direct visualization of engrafted murine GFP<sup>+</sup> HSC in candidate niches of the mouse bone has been obtained (Yoshimoto *et al.*, 2003). In myeloablative conditions, GFP<sup>+</sup> foci were first detected at the femoral epiphyses and some ribs and vertebra and thereafter spread to other bones. In nonmyeloablative transplants GFP<sup>+</sup> cells localized in femoral epiphyses and in some vertebra and ribs but remained quiescent for at least four months, presumably due to residence in quiescent niches (Fig. 49.2). Primitive hematopoietic cells, including HSC, are retained in the endosteal niche, whereas lineage-committed cells localize to the central marrow regions (Nilsson *et al.*, 2003) (Fig. 49.4). These two populations display striking differences in the expression of cell surface adhesion molecules. Murine SLAMF2 CD150-expressing HSC localize in various sites after *in vivo* injection, including endothelial niches provided by the sinusoids of spleen and marrow as well as endosteal niches (Fig. 49.4) (Kiel *et al.*, 2005). The presence of glycosaminoglycan hyaluronic acid on HSC appears critical for the spatial distribution of transplanted stem cells *in vivo*. Furthermore, binding of hyaluronic acid by a surrogate ligand results in marked inhibition of HSC proliferation and granulocyte differentiation. A unique feature of the bone niche for HSC is the high concentration of calcium ions at the endosteal surface. HSC express a calcium-sensing receptor (CaR), and mice defi-

**FIG. 49.4.** Human CD34<sup>+</sup>/CXCR4<sup>+</sup> HSC from the circulation transit the BM sinusoids comprising the endothelial niches and home to the endosteal niche. Interactive molecules are shown that are expressed either on the HSC or on the immature osteoblasts.

cient in CaR had normal numbers of HSC in the fetal liver but were highly deficient in HSC localizing to the endosteal niche (Adams *et al.*, 2006).

Further evidence for the importance of the osteoblast niche has been provided in studies in mice with genetic modifications leading to increased numbers of osteoblasts. Mice with constitutively activated parathyroid receptors have enhanced numbers of osteoblasts associated with a doubling of BM Sca-1<sup>+</sup>c-Kit<sup>+</sup>Lin<sup>-</sup> cells and increased LTC-IC and long-term repopulating HSC (Calvi *et al.*, 2003). Osteoblasts with activated receptors produced high levels of the Notch ligand Jagged1, which may be responsible for HSC expansion, since HSC expansion was abrogated following treatment with a gamma secretase inhibitor that blocked Notch activation. Mutant mice with conditional inactivation of the BMP receptor 1A led to an increase in the number of

spindle-shaped N-cadherin<sup>+</sup>, CD45<sup>-</sup> osteoblasts (J. Zhang *et al.*, 2003). This was linked to a 2.4-fold increase in quiescent HSC and competitive repopulating cells in the marrow. Since β-catenin forms a complex with N-cadherin, this may play a role in retaining HSC in osteoblastic niches (Fig. 49.4).

A quiescent state is probably critical for maintenance of HSC. HSC expressing the Tie2 receptor are quiescent and antiapoptotic and comprise a side population that adheres to osteoblasts in the BM niche (Arai *et al.*, 2004). The Tie-2 ligand, angiopoietin-1, induced HSC quiescence, their adherence to the endosteal surface, cobblestone formation, and retention of long-term repopulating activity (Fig. 49.2). The matrix glycoprotein, osteopontin (OPN), acts as a negative regulatory restraining factor on HSC within the osteoblast niche (Stier *et al.*, 2005; Nilsson *et al.*, 2005). Osteoblasts at the endosteal bone surface produce varying amounts of osteopontin in response to stimulation and HSC specifically bind to OPN via β1 integrin. Exogenous OPN potently suppresses the proliferation of HSC *in vitro*, and OPN-deficient mice have increased numbers of HSC with markedly enhanced cycling.

c-Myc appears to control the balance between HSC self-renewal and differentiation, possibly by regulating the interaction between HSC and their niches (Wilson *et al.*, 2004). Conditional elimination of c-Myc activity in BM resulted in severe cytopenia and accumulation of self-renewing HSC *in situ*, with impaired differentiation. The c-Myc-deficient HSC appear trapped in stem cell niches, possibly due to up-regulation of N-cadherin and a number of adhesion molecules. Enforced c-Myc expression in HSC repressed N-cadherin and integrins, leading to loss of self-renewal at the expense of differentiation.

## IX. CONCLUSION

The current dogma recognizes that specific factors determine specific cell fates, ranging from stem cell (HSC) self-renewal through commitment to common myeloid (CMP) or common lymphoid progenitors (CLP) to lineage-restricted progenitor differentiation. A contrary hypothesis to current dogma recognizes that HSC fate may instead be governed by (small) quantitative shifts in the relative activation of known signaling pathways (Davey and Zandstra, 2004). Alterations in the relative levels of pathway activation may arise from dynamic shifts in the expression of signaling components (e.g., receptors, ligands). Because extracellular conditions vary over small ranges, cells are induced to overcome signaling threshold barriers and, as a consequence, adopt new, stable cell fates. *Ex vivo* HSC culture systems can be manipulated (1) quantitatively, e.g., by varying the magnitude of signaling pathway activation, influencing cell fate decisions; (2) temporally, e.g., by defining windows of opportunity for stimulation; and (3) spatially, e.g., by fixed location-dependent signaling (niches).

### I. INTRODUCTION

Hemoglobin molecules extracted from red blood cells are modified by microencapsulation or cross-linking. This stabilizes the hemoglobin molecules and also allows the sterilization of the product to remove HIV and other microorganisms. A number of modified hemoglobin molecules have been developed, and extensive clinical trials have been carried out. These clinical studies have led to the recent finding that it is important to have nanodimension-modified hemoglobin in order to avoid problems related to vasoconstriction caused by the removal of nitric oxide. Although development toward routine clinical uses of blood substitutes is complex and slow, one type of nanodimension polyhemoglobin has been approved for routine clinical uses in South Africa and in Phase III clinical trials in North America. New generations of modified hemoglobin are also being actively developed, including nanodimension polyhemoglobin-catalase-superoxide dismutase, nano-artificial red blood cells of lipid or biodegradable polymeric membrane, and others.

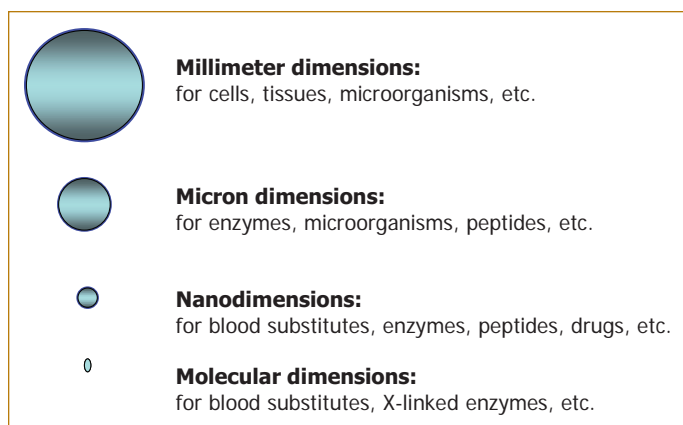

In 1957, the author initiated the first research on artificial cells including modified hemoglobin (Chang, 1957). Artificial cells (Fig. 50.1) retain biologically active materials such as hemoglobin, enzymes, cells, and adsorbent and other materials (Chang, 1964, 1972, 2005, 2007). Their dimensions can vary in the macro, micro, nano, and molecular ranges (Fig. 50.2). The membrane of artificial cells

allows permeable molecules such as oxygen and substrates to enter and products, peptides, and other materials to leave. In this way the enclosed materials are protected from immunological rejection and other materials from the external environment. Until 1989, most research was on artificial cells containing enzymes, cells, microorganisms, adsorbents, peptides, and others.

Concentrated research and development on modified hemoglobin started only after 1987 because of public concerns of HIV in donor blood. After extraction from red blood cells and before modification, hemoglobin can be sterilized by pasteurization, ultrafiltration, and chemical means. These procedures can remove microorganisms, including those responsible for AIDS, hepatitis, and other diseases. There are many situations where modified hemoglobin can potentially be used to substitute for red blood cells (Chang, 1997, 2003, 2004, 2005; Klein, 2000; Rudolph *et al.*, 1997; Tuschida, 1998; Kobayashi *et al.*, 2005; Winslow, 2003, 2006). These include trauma surgery, cardiopulmonary bypass surgery, cancer surgery, other elective surgery, and cardioplegia. Another area is in severe traumatic injuries, such as traffic accidents and other accidents that result in severe bleeding and hemorrhagic shock. The number of traumatic injuries requiring blood substitutes in civilian use is small when compared to the requirements in major disasters or wars. Modified hemoglobin is especially useful in emergency situations such as these. Since modified

hemoglobin does not contain red blood cell membrane and therefore no blood group antigens, it can be used without the need for cross-matching or typing. This could save much time and facilities and would permit on-the-spot transfusion as required, similar to giving intravenous solution. This is further facilitated by the fact that modified hemoglobin can be stored as a solution at room temperature for more than two years. It can also be lyophilized and stored as a stable dried powder that can be reconstituted with the appropriate salt solution just before use. Another requirement is where the patients' religious belief does not allow them to use donor blood for transfusion.

## II. MODIFIED HEMOGLOBIN

### Why Do We Have to Modify Hemoglobin?

Hemoglobin in the red blood cell is responsible for carrying oxygen from the lung and delivering oxygen to tissues. It is a tetramer of four subunits: two alpha subunits and two beta subunits (Perutz, 1989) (Fig. 50.3). Hemoglobin is in the

**FIG. 50.3.** Inside the red blood cell, each hemoglobin molecule is a tetramer of four subunits: two alpha subunits and two beta subunits. Cofactors 2,3-DPG, retained in the red blood cell, help the hemoglobin to release oxygen as required by the tissues. An artificial red blood cell has the same content as red blood cells, but the membrane is made of synthetic material. Modified from Chang (1992), with permission of Marcel Dekker, Publisher.

“oxy,” relaxed, or “R” state when it is carrying oxygen. To release oxygen, the hemoglobin molecule undergoes conformational change with a 15° rotation. The molecule is then in the “deoxy,” tensed, or “T” state. Red blood cells contain a cofactor, 2,3-DPG, which facilitates this conformational change. Thus, hemoglobin inside red blood cells has a high  $P_{50}$ , which allows it readily to release oxygen to the tissue at physiological oxygen tensions.

Hemoglobin can be extracted from red blood cells by removing the cell membranes to form stroma-free hemoglobin. Attempts in clinical trials in patients to use stroma-free hemoglobin as a blood substitute were not successful because of renal toxicity and other adverse effects (Savitsky *et al.*, 1978). When infused into the circulation, each hemoglobin molecule of four subunits (tetramer) is rapidly broken down into two subunits (dimers). These toxic dimers are the major causes of the adverse effects.

### Modified Hemoglobin

Biotechnological approaches can be used either to cross-link or to encapsulate the hemoglobin molecules, to prevent hemoglobin from dissociating into dimers and also to allow hemoglobin to have an acceptable  $P_{50}$  (Chang, 1957, 1964, 1971, 1972). Many groups have since contributed to major progress, especially since around 1990. These include Abuchowski, Agishi, Alayash, Bakker, Benesch, Biro,

Bonhard, Bucci, Bund and Jandl, Chang, DeAngelo, D'Agnillo, DeVenuto, Estep, Faivre, Farmer, Feola, Fratanoni, Fronteicelli, Gould, Greenburg, Hedlund, Hess, Hori, Hsia, Iwashita, Jesch, Kobayashi, Keipert, Klugger, Liu, Manning, Messmer, Moss, Nose, Olson, Privalle, Pristoupil, Rudolph, Segal, Sekiguchi, Sideman, Shorr, Valeri, Winslow, Wong, and Yang, among many others. Microencapsulation of hemoglobin to prepare artificial red blood cells (Chang, 1957, 1964) is a rather ambitious approach (Fig. 50.3). Although this attempt to mimic red blood cells has resulted in a complete red blood cell substitute, it is rather complicated. Further research is needed. This approach, now considered a third-generation modified hemoglobin, is discussed later. Simpler cross-linked modified hemoglobin has been developed as a first-generation modified hemoglobin for more immediate clinical applications, as discussed next.

### III. FIRST-GENERATION MODIFIED HEMOGLOBIN

#### Polyhemoglobin Based on Nanobiotechnology

Hemoglobin contains numerous amino groups, many of which are on the surface of the hemoglobin molecule. This author first reported the use of nanobiotechnology with a bifunctional agent (diacid) to cross-link and assemble hemoglobin molecules into polyhemoglobin (Chang, 1964, 1972) (Fig. 50.4). This was used first to form ultrathin polyhemoglobin membranes for artificial red blood cells. It was also found that by decreasing the size of artificial cells,

all the hemoglobin molecules become cross-linked into polyhemoglobin. Cross-linking prevents the breakdown of hemoglobin tetramers into dimers. The reaction is as follows (Chang, 1964, 1972):

Glutaraldehyde is another bifunctional agent first used by this author in a similar nanobiotechnological approach to cross-link and assemble hemoglobin molecules into soluble nanodimension polyhemoglobin (Chang, 1971):

Since then, a number of other groups have independently carried out extensive studies using this principle of glutaraldehyde-cross-linked polyhemoglobin. The two most successful are glutaraldehyde-cross-linked human polyhemoglobin (Gould *et al.*, 1998, 2002) and glutaraldehyde-cross-linked bovine polyhemoglobin (Pearce and Gawryl, 1998; Sprung *et al.*, 2002). Another glutaraldehyde polyhemoglobin uses hemoglobin from red blood cells of placentas discarded after birth (T. Li *et al.*, 2006). Other cross-linkers have also been developed.

#### Intramolecularly Cross-Linked Hemoglobin

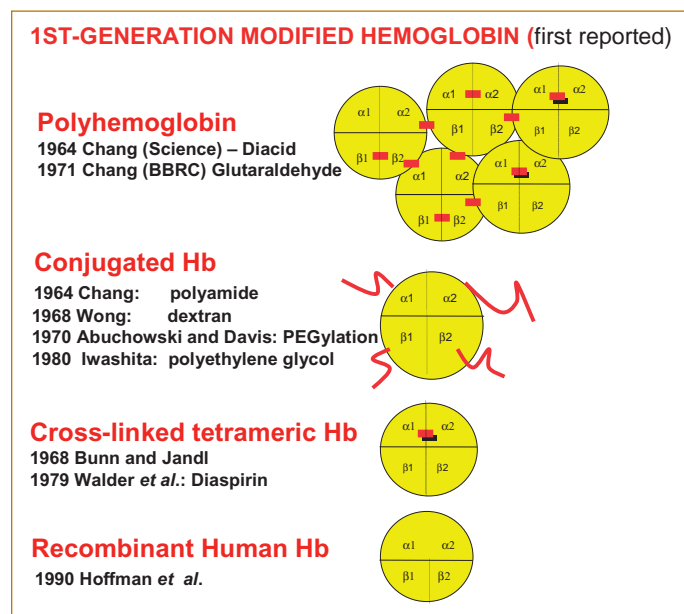

Studies have been carried out specifically to cross-link hemoglobin molecules intramolecularly to form cross-linked tetrameric hemoglobin (Fig. 50.4). For example, a bifunctional agent, 2-Nor-2-formylpyridoxal 5-phosphate, which is also a 2,3-DPG analog, can intramolecularly cross-link the two beta subunits of the hemoglobin molecules (Bunn and Jandl, 1968). Another 2,3-DPG pocket modifier, bis(3,5-dibromosalicyl) fumarate (DBBF), intramolecularly cross-links the two alpha subunits of the hemoglobin molecule (Walder *et al.*, 1979; Nelson, 1998).

#### Conjugated Hemoglobin

Conjugated hemoglobin involves the cross-linking of hemoglobin to polymers (Chang, 1964, 1972). The use of soluble polymers resulted in soluble conjugated hemoglobin with good circulation time (Iwashita, 1992; Wong, 1988). Two new nanodimension conjugated hemoglobin molecules are being tested in ongoing clinical trials (X. Z. Li *et al.*, 2005; Winslow, 2003, 2006).

#### Sources of Hemoglobin

Where do we obtain all the hemoglobin needed for preparing modified hemoglobin? Red blood cells from outdated donor blood is one major source of human hemoglobin. Another source is human hemoglobin from red blood cells

**FIG. 50.4.** Molecular-dimension red blood cell substitutes in the form of polyhemoglobin, conjugated hemoglobin, intramolecularly cross-linked hemoglobin, and recombinant hemoglobin. Modified from Chang (2004), with copyright permission from Marcel Dekker, Publisher.

of placenta discarded after the delivery of babies (T. Li *et al.*, 2006). In addition to hemoglobin from human sources, another source is bovine hemoglobin (Pearce and Gawryl, 1998). Another promising source is human hemoglobin produced by recombinant technology in microorganisms (Frontecelli *et al.*, 2004; Freytag and Templeton, 1997; Hoffman *et al.*, 1990). One of these has been tested in clinical trials (Frytag and Templeton, 1997), and the result of clinical trials has led to the development of a second-generation recombinant human hemoglobin (Doherty *et al.*, 1998). Another potential source that is being developed is synthetic heme, which is linked to recombinant human albumin (Tsuchida, 1998; Tsuchida *et al.*, 2002).

### Efficacy and Safety of Modified Hemoglobin Blood Substitutes

Modified hemoglobin no longer has problems related to the breakdown of hemoglobin into toxic dimers. However, how safe is modified hemoglobin when injected into animals and humans? Animal studies using properly prepared modified hemoglobin have shown no adverse effects on coagulation factors, leucocytes, platelets, or complement activation (Chang, 1997, 2003, 2004, 2005; Klein, 2000; Rudolph *et al.*, 1997; Tsuchida, 1998; Kobayashi *et al.*, 2005; Winslow, 2003, 2006). Very severe and sensitive immunological studies have been carried out for polyhemoglobin, conjugated hemoglobin, and microencapsulated hemoglobin (Chang *et al.*, 1992; Chang, 1997). Results show that modified homologous polyhemoglobins (e.g., rat polyhemoglobin injected into rats) are not immunogenic, even with repeated injection. Heterologous polyhemoglobin (e.g., nonrat hemoglobin injected into rats) is not immunogenic initially but is immunogenic after repeated injections with Freund's adjuvant. Conjugation and microencapsulation markedly decreased the antigenicity of heterologous polyhemoglobin. Other studies show that without the use of Freund's adjuvant, repeated subcutaneous and intravenous injections of heterologous cross-linked hemoglobin are much less immunogenic (Estep *et al.*, 1992).

Another important area of safety study is the distribution of modified hemoglobin after infusion and also its effect on the reticuloendothelial system. Another factor is that the safety response in animals is not necessarily the same as in humans, especially in the case of immunological and hypersensitivity types of reactions. We have worked out a simple *in vitro* screening test (Chang, 1997), which consists of adding 0.1 mL of modified hemoglobin to a test tube containing 0.4 mL of human plasma or blood and then analyzing for complement activation. This has been used to detect trace contamination of blood group antigens, antibody-antigen complexes, endotoxin, trace fragments of microorganisms, impurities in polymers, some emulsifiers, and others. Detailed animal studies show that modified hemoglobins are effective in short-term applications such as hemorrhagic shock, exchange transfusion, hemodilution

in surgery, and some other conditions. However, despite all the detailed *in vitro* and *in vivo* safety and efficacy studies and screening tests, as just described, extensive clinical trials since the early 1990s show that some of the blood substitutes have problems related to increased vasoconstriction, as discussed next.

### Vasoactivity and Nitric Oxide

Not all modified hemoglobins have been successful in clinical trials, since a vasopressor effect has been observed in some of the first-generation modified hemoglobin blood substitutes. For example, intramolecularly cross-linked hemoglobin and first-generation recombinant human hemoglobin blood substitutes contain 100% molecular-dimension modified hemoglobin. Infusion causes vasopressor effects and also increased smooth muscle contractions. With another type of polyhemoglobin, which contains more than 30% molecular-dimension modified hemoglobin, significant vasoactivity and increased smooth muscle contractions can also be observed when using larger volumes. On the other hand, the use of nano-dimension polyhemoglobin with <1% molecular-dimension modified hemoglobin did not show vasopressor effects, even when large volumes of 10 liters were infused. This has led to the proposal that the intercellular junctions of the endothelial lining of vascular wall allow molecular-dimension hemoglobin to enter the interstitial space (Fig. 50.5). There, hemoglobin acts as a sink in binding and removing the nitric oxide needed for maintaining the normal tone of smooth muscles. This results in the constriction of blood vessels and other smooth muscles, especially those of the esophagus and the GI tract. On the other hand, nano-dimension polyhemoglobin would not cross the intercellular junction and therefore does not result in vasoconstriction (Fig. 50.5). Others argue that one cannot compare the different types of modified hemoglobin, since there are major differences in the chemistry involved and in oxygen affinity. We therefore prepare laboratory versions of nanodimension polyhemoglobin, each containing a different percentage of molecular-dimension hemoglobin, using the same glutaraldehyde cross-linking and characterized to ensure that they all have the same oxygen affinity (B. L. Yu *et al.*, 2006). The result shows that samples with a very low percentage of molecular-dimension modified hemoglobin do not cause vasoconstriction or changes in electrocardiogram. Increasing the percentage of molecular-dimension modified hemoglobin yielded an increasing degree of vasoconstriction and elevation of the ST segment of the electrocardiogram. ST elevation could be due to vasoconstriction, resulting in a decreased supply of oxygen to the heart, which may explain the observation of small myocardial lesions in some primates and swine after infusion with one type of molecular-dimension modified hemoglobin (Burhop and Estep, 2001). This theory is further supported by the lack of vasoconstriction using nonextravasating hemoglobin

**FIG. 50.5.** Molecular-dimension modified hemoglobin can transverse the intercellular junction of the endothelial cells of the vascular wall. It will then bind with nitric oxide, thus removing it and resulting in increased vasoactivity, since removal of nitric oxide results in contraction of smooth muscles of the vascular wall and other smooth muscles. Nanodimension modified hemoglobin molecules do not contain any significant free molecular-dimension modified hemoglobin. They cannot transverse the intercellular junction and therefore do not cause vasoconstriction. From Chang (1997), with permission of the copyright holder.

polymer (Matheson *et al.*, 2002). Furthermore, a second-generation molecular-dimension recombinant human hemoglobin that did not bind nitric oxide did not cause vasoconstriction (Doherty *et al.*, 1998). Since recombinant hemoglobin crosses the intercellular junction and is removed quickly, the circulation time can be increased by cross-linking to form nanodimension polyhemoglobin (Fronticelli *et al.*, 2004). Another approach in an ongoing clinical trial is to prepare PEG-conjugated hemoglobin that, with its water of hydration, would result in a nanodimension modified hemoglobin, and this does not result in vasopressor effects (Winslow, 2006).

### Present Clinical Status of First-Generation Modified Hemoglobin

Two of the most successful ones are based on glutaraldehyde-cross-linked polyhemoglobin. These were developed independently by two groups based on Chang's basic principle of glutaraldehyde-cross-linked polyhemoglobin (Chang, 1971). One is pyridoxalated glutaraldehyde human polyhemoglobin (Gould *et al.*, 1998, 2002). The researchers show in Phase III clinical trials that this can successfully replace extensive blood loss in trauma surgery by maintaining the hemoglobin level, with no reported side effects (Gould *et al.*, 2002). They have infused up to 10 liters into individual trauma surgery patients. Another one is glutaraldehyde-cross-linked bovine polyhemoglobin, which has been extensively tested in clinical trials (Pearce and

	DONOR RBC	BLOOD SUBSTITUTES (Polyhemoglobin)
INFECTION	Possible	Sterilized
SOURCE	Limited	"Unlimited"?
BLOOD GROUPS	Yes	None
USAGE	Xmatch, typing	Immediately
STORAGE	42 days	>1 year
FUNCTIONS	RBC	Oxygen carrier

**FIG. 50.6.** Comparison of polyhemoglobin with donor red blood cells. Polyhemoglobin has many advantages over red blood cells and is useful during surgery. However, it cannot be used in a number of other clinical conditions, because, unlike red blood cells (rbc), polyhemoglobin is only an oxygen carrier. It has no rbc enzymes needed for many functions, including the removal of oxygen radicals. Furthermore, its circulation time is much shorter than that of rbc. Modified from Chang (2004), with copyright permission from Marcel Dekker, Publisher.

Gawryl, 1998; Sprung *et al.*, 2002). This bovine polyhemoglobin has been approved for routine patient uses in South Africa. These two polyhemoglobins have been approved for compassionate use in humans, and they are awaiting regulatory approval for routine clinical use in humans in North America. Conjugated hemoglobin of sufficient nano-dimension is another promising approach that is in phase II clinical trials (Winslow, 2006).

Nanodimension polyhemoglobin and conjugated hemoglobin have a number of advantages when compared to donor red blood cells (Fig. 50.6). Unlike red blood cells, there is no blood group, and thus it can be given immediately on the spot without time-consuming typing and cross-matching. It can be sterilized and is free of infectious agents. Donor blood has to be stored at 4°C and is good for only 42 days. Polyhemoglobin can be stored at room temperature for more than a year. Thus, it has an important role in a number of clinical conditions. In some other conditions, related to severe and sustained ischemia, we may have to add antioxidant enzymes to oxygen carriers in order to avoid the potential for ischemia reperfusion injury (Fig. 50.7).

## IV. NEW GENERATIONS OF MODIFIED HEMOGLOBIN

### Polyhemoglobin Cross-Linked with RBC Antioxidant Enzymes

In sustained severe hemorrhagic shock or other ischemic conditions, oxygen carrier alone may result in ischemia reperfusion injuries, due to the production of oxygen

**FIG. 50.7.** Cross-linking of hemoglobin with two rbc enzymes to form polyhemoglobin-catalase-superoxide dismutase (PolyHb-CAT-SOD). Unlike polyhemoglobin, this has rbc enzymes that can remove oxygen radicals. Modified from Chang (2004), with copyright permission from Marcel Dekker, Publisher.

**FIG. 50.8.** In conditions such as severe sustained hemorrhagic shock, stroke, myocardial infarction, and organ transplantation, reperfusion with polyhemoglobin can sometimes result in oxygen radicals that cause tissue injury. PolyHb-CAT-SOD can supply oxygen and at the same time significantly lower any oxygen radicals formed. From Chang (1997), with copyright permission from the copyright holder.

radicals (Fig. 50.8) (Alayash, 2004; Chang, 2003). We are studying the use of a cross-linked polyhemoglobin-superoxide dismutase-catalase (PolyHb-SOD-CAT) (Fig. 50.7) (D'Agnillo and Chang, 1998). The intestine is one of the organs most likely to be injured in this type of ischemia reperfusion injury. We found that, unlike PolyHb, PolyHb-SOD-CAT did not cause a significant increase in oxygen radicals when used to reperfuse ischemic rat intestine (Chang, 1997). Polyhemoglobin is in solution and is therefore more likely to be able to perfuse partially obstructed vessels in stroke, myocardial infarction, and other conditions as compared to red blood cells. In a rat stroke model (Fig. 50.9), we found that after 60 minutes of ischemia, reperfusion with polyHb resulted in a significant increase in the breakdown of blood-brain barrier and an increase in brain edema (Powanda and Chang, 2002). On the other hand, polyHb-SOD-CAT did not result in these adverse changes (Powanda and Chang, 2002).

**FIG. 50.9.** This is a rat model of acute global cerebral ischemia followed by reperfusion with different oxygen-carrying solutions. Unlike polyhemoglobin, polyHb-CAT-SOD does not cause brain edema when used in this situation. From Powanda and Chang (2002), with copyright permission from Marcel Dekker, Publisher.

### Polyhemoglobin Cross-Linked with Tyrosinase

Tumors are not well perfused with blood, but radiation therapy and chemotherapy work better with better tissue oxygenation. Since polyhemoglobin is in solution, it can perfuse tumor more effectively than red blood cells and thus has been studied for potential use in radiation therapy and chemotherapy of tumors (Shorr *et al.*, 1996; Pearce and Gawryl, 1998). We have recently cross-linked tyrosinase with hemoglobin to form a soluble polyhemoglobin-tyrosinase complex (B. L. Yu and Chang, 2004). This has the potential dual function of supplying the needed oxygen for radiation therapy and in addition lowers the systemic tyrosine needed for the growth of melanoma. This preparation inhibits the growth of murine B16F10 melanoma culture. In mice, it significantly delays the growth of B16F10 melanoma as compared to the control group, without causing adverse effects or changes in the growth of the treated animals (B. L. Yu and Chang, 2004).

### Artificial Red Blood Cells

The first artificial red blood cells (Figs. 50.1 and 50.3) have an oxygen dissociation curve similar to that for red blood cells, since 2–3-DPG is retained inside (Chang, 1957). Hemoglobin also stays inside as tetramers, and red blood cell enzymes such as carbonic anhydrase and catalase retain their activities (Chang, 1964, 1972). These artificial red blood cells do not have blood group antigens on the membrane and therefore do not aggregate in the presence of blood group antibodies (Chang, 1972). However, the single major problem is the rapid removal of these artificial cells from the circulation. Most of the studies since that time aimed to improve survival in the circulation by decreasing uptake by

the reticuloendothelial system. Since removal of sialic acid from biological red blood cells resulted in their rapid removal from the circulation, we started to modify the surface properties of artificial red blood cells (Chang, 1972). This included synthetic polymers, negatively charged polymers, cross-linked protein, lipid-protein, lipid-polymer, and others. Artificial red blood cells have since been extensively explored by many researchers around the world. These include Beissinger, Chang, Farmer, Hunt, Kobayashi, Lee, Mobed, Nishiyia, Rabinovic, Rudolph, Schmidt, Sinohara, Szebeni, Takeoka, Tsuchida, Takahashi, and Usuba, among many others.

One major area of progress is the preparation of submicron lipid membrane artificial red blood cells, resulting in significant improvements in circulation time (Djordjevic and Miller, 1980). By the addition of polyethylene glycol to the lipid membrane, the circulation time has been increased to a half-time of about 36 hours in rats (Philips *et al.*, 1999). These advances now make it possible to scale-up for detailed preclinical studies toward clinical trials (Tsuchida, 1998; Kobayashi *et al.*, 2005). The uptake is mainly by the reticuloendothelial system. It is possible to replace 90% of the red blood cells in rats with these artificial red blood cells. The animals with this percentage of exchange transfusion remain viable. Studies also reported effectiveness in hemorrhagic shock. There are no changes in the histology of brain, heart, kidneys, and lungs of rats.

Using a modification of this author's earlier method of micron-dimension biodegradable polymeric membrane artificial cells (Chang, 1976), we recently prepared nanodimension artificial red blood cells (Chang, 1997, 2003; W. P. Yu and Chang, 1996). These nano-artificial rbc of 80–150 nanometers contain all the red blood cell enzymes and can convert methemoglobin to hemoglobin (Chang *et al.*, 2003) (Fig. 50.10). Our recent studies show that, using a polyethylene-glycol-poly lactide copolymer membrane, we are able to increase the circulation time of these nano-artificial red blood cells to double that of polyhemoglobin (Fig. 50.11) (Chang *et al.*, 2003). Further studies show that one infusion with a volume of one-third the total blood volume resulted in no adverse effects.

## V. A CHEMICAL APPROACH BASED ON PERFLUOROchemicals

There is another type of blood substitute, based on a chemical approach first shown by Clark and then Geyer using perfluorochemicals (Riess, 2001). This approach was developed by a number of investigators, including Chen, Clark, Geyer, Faithful, Keipert, Lowe, Mitsuno, Naito, Nose, Ohyanagi, Riess, Sloviter, and Yokoyama, among many others. Perfluorochemicals (PFCs) are synthetic fluids in which oxygen can dissolve and that can be made into fine emulsions for use as oxygen carriers. Their greatest advantage is that they can be produced in large amounts. Further-

**FIG. 50.10.** Nanodimension artificial red blood cells with polyethylene-glyco-poly lactide membrane. In addition to hemoglobin, this contains the same enzymes that are normally present in red blood cells. Thus, it has the complete function of red blood cells. From Chang *et al.* (2003), with copyright permission from Marcel Dekker, Publisher.

more, their purity can be more easily controlled. However, PFCs have a lower capacity for carrying oxygen than Hb. Improved perfluorochemicals have allowed a higher concentration of PFC to be used and a blood substitute based on perfluoro-octyl bromide (C<sub>8</sub>F<sub>17</sub>Br) with egg-yolk lecithin as the surfactant has been tested in clinical trials. The results are being carefully analyzed.

## VI. CONCLUSIONS

It was mistakenly thought that blood substitute would be a simple approach that could easily be developed for clinical applications when needed. Thus, the crisis of HIV-contaminated donor blood was followed by efforts to be able to quickly manufacture blood substitutes for clinical use. However, many years have passed with numerous failures, and no blood substitute is yet in routine clinical use in North America, and only one type of first-generation material is in the final phases of Phase III clinical trials. We now know that we have to approach blood substitutes as a highly interdisciplinary type of basic and applied research and development involving polymer chemistry, cell physiology, molecular biology, biotechnology, and other areas. The belated but ongoing emphasis on this interdisciplinary approach will accelerate the clinical realization of blood substitutes. This brief overview cannot include the numerous ongoing studies and research in this area. More details are available in the many detailed publications, books, and symposium volumes in this area (Chang, 1997, 2003, 2005, 2007; Klein, 2000; Rudolph *et al.*, 1997; Tsuchida, 1998; Kobayashi *et al.*, 2005; Winslow, 2003, 2006).

**FIG. 50.11.** Nanodimension artificial red blood cells with polyethylene-glyco-polylactide membrane. The circulation time is double that of polyhemoglobin. The circulation half-time of polyhemoglobin in human is about 24 hours. This means that the nanodimension artificial rbc may have a circulation time of about 48 hours in human. ### I. INTRODUCTION

For researchers interested in cell-based therapy, it is a great challenge to learn how to expand normal lymphoid cells and their precursor cells *ex vivo* under defined conditions. Lymphocytes are defined by cell surface receptor-immunoglobulin (Ig) for B-cells and the T-cell receptor (TCR) for T-cells. Precursor B-cells bear a pre-B receptor, which contains lambda 5 in mice ("physi" in humans), and precursor T-cells bear a pre-TCR-alpha. No biochemically and genetically defined surface receptors for the progenitors of lymphoid precursors have been reported. It is not entirely clear how committed stem cells differentiate into lymphoid cells, which then mature into effector cells. Many theories have been postulated. Differentiation and maturation involve both antigen-independent and antigen-dependent processes. For the first process, I will explore the sequential commitment model proposed by Brown *et al.* (1985, 1988). For my treatment of the second process, I am indebted to many colleagues who helped me to summarize current views.

Ligand-receptor interactions must play an important role in activating lymphoid cells to proliferate and to differ-

entiate. The term *ligand* means all external signals, including those provided by stroma cells and cytokines during the antigen-independent stage and those provided by antigens (Ag) and antigen-presenting cells (APCs), or accessory cells during the antigen-dependent stage. The process of turning on and turning off of transcription factors at each stage of differentiation as a consequence of ligand-receptor interaction is the key element controlling both the phenotype and the function of cells. I will discuss transcription factors known to be important at various stages of lymphopoiesis due to the notion that the growth of lymphoid (precursor) cells can be manipulated at will by using genetic tools. There are a few examples of expansion of normal lymphoid (precursor) cells in culture. All are based on the support of stroma cell lines and cytokines. On removal of these elements, cells either differentiate toward terminal effector cells or die.

I have arbitrarily defined seven stages of lymphopoiesis to discuss in detail. For each one, I discuss the available cellular and molecular markers, the current understanding of cellular phenotype, the potential of these cells to expand *ex vivo*, and, if possible, what could be done in the future.

Both somatic and genetic manipulations are possible in animal models. By combining modern cellular technology and available mutant mice, one should be able to grow normal lymphoid (precursor) cells at every stage of lymphopoiesis.

Despite the efforts of many, human stroma cell lines that can reproducibly support the growth of different stages of lymphoid (precursor) cells are still under development. To apply inducible regulation of stage-specific and lymphoid-specific transcription factors in controlling the growth of normal lymphoid cells seems to be the key element.

The aim of this chapter is to understand lymphocytes and their precursors. The purpose is to learn how these cells might be manipulated to make them useful in cell-based, somatic gene therapy. I attempt to address the possibility of growing normal lymphoid cells and their stem cells of mouse and human origin in a controllable manner. That is, cells should proliferate *ex vivo* without becoming malignantly transformed and with little or no differentiation.

Three main types of stem cells can be distinguished: totipotent, pluripotent, and multipotent. Totipotent and pluripotent stem cells usually divide symmetrically to give rise to two daughter stem cells with the same properties that are identical in phenotype to their parent. Under appropriate conditions, totipotent and pluripotent stem cells can differentiate into any other form of stem cell. The only known stem cell lines that seem to be close to totipotent are mouse embryonic stem cells (ESCs) and, more recently, human ESCs. Multipotent stem cells, which exist for the lifetime of an organism, undergo primarily asymmetric divisions. One daughter cell is another stem cell like its parent, whereas the other daughter cell is a more highly differentiated cell that performs a tissue-specific function. Due to this unique property, multipotent stem cells are ideal vehicles for cell-based, somatic gene therapy. They will carry the transgene for the lifetime of the organism, and they will maintain expression of the transgene in the differentiated cells that they spawn.

Both lymphoid and lymphoid precursor cells are the progenies of hematopoietic stem cells (HSCs). One of the main tasks here is to review whether lymphoid cells and their progenitors possess stem cell-like properties. Are they self-renewing? And with available culture conditions and technology, can they expand *ex vivo* under controllable growth conditions? Unlimited growth of lymphoid cells and their progenitors is well documented. Lymphoid leukemia cells develop either spontaneously or after infection with viruses. These cell lines are useful for studying lymphoid cells but not for cell-based therapy, because they develop tumors when reintroduced into the organism. Thus, this chapter is devoted to exploring the possibility of growing normal lymphoid cells that can be engineered in culture and reimplanted into syngeneic or autologous hosts for therapeutic purposes. Other normal cell types, expandable

at will using genetic approaches, are available: tet-on (tetracycline-inducible) glial stem cells (Muth *et al.*, 2001; Elmshaeuser *et al.*, 2002) and tet-off (tetracycline-regulated) keratinocytic and lung stem cells (Chen, 2001, 2006a, 2006b).

## II. PROPERTIES OF LYMPHOCYTES

Lymphoid precursor cells are bipotent progenitors of pre-T- and pre-B-cells. The development of lymphoid precursor cells is independent of the presence of Ag. It is controversial whether lymphoid precursor cells divide asymmetrically with self-renewal. Lymphocyte types are defined by cell surface receptors-Ig for B-cells and the TCR for T-cells. Precursor B-cells bear a pre-B receptor, which contains lambda 5 in mice, and “physi” in humans, and precursor T-cells bear a pre-TCR- $\alpha$ . So far, no biochemically and genetically defined surface receptors for the progenitors of lymphoid precursors have been reported. Lymphocytes and their precursors are similar to cells of other lineages, in that they proliferate, differentiate, communicate with other cells, age, and die. However, lymphocytes also possess unique properties that distinguish them from other cells: (1) formation of receptor genes by VDJ recombination, (2) requirement for a thymuslike environment to generate mature CD4<sup>+</sup>/8<sup>+</sup> T-cells, (3) requirement for somatic education and selection by Ag, (4) somatic hypermutation to generate more diversity in B-cells, (5) immunologic memory, (6) Ig heavy-chain class switch recombination in B-cells, and (7) kappa light-chain editing somatically to generate new specificities of B-cell receptor (Chen, 2000). Development of techniques to expand *ex vivo*, to manipulate genetically, and to reimplant lymphocytes and their precursors into host animals requires lymphocyte engineers.

## III. LYMPHOCYTE ENGINEERING: REALITY AND POTENTIAL

Two models describe the sequence of cell commitment during lymphopoiesis: stochastic and inductive. In this section, I use an inductive model in an attempt to explain lymphocyte commitment during development of the organism and in the adult.

## IV. INDUCTIVE MODEL OF SEQUENTIAL CELL COMMITMENT OF HEMATOPOIESIS

This model is divided into two parts. The first part deals with the Ag-independent stage, starting with the differentiation from the null cells (fertilized egg to embryonic stem cells) to mesoderm and then to lymphoid precursor cells. A significant portion of the first part of this model was expanded from Bailey’s hypothesis of developmental progress (1986) and modified according to Brown *et al.* (1985, 1988).

### Antigen-Independent Stage of Lymphopoiesis – Part 1

Because multipotential stem cells are committed to differentiate, it is hypothesized that the differentiation sequence is genetically determined. Cells within the sequence are precommitted in how they're determined. Cells within the sequence are precommitted in their ability to respond to various inducers of differentiation; and on encountering appropriate factors or a suitable microenvironment, they proliferate and mature along a particular pathway. It is proposed that multipotential stem cells that do not receive a signal for differentiation toward mature end cells progress to the next stage in the sequence of development. Alternatively, cells that do not receive a signal die. Only cells that receive proper signals will differentiate further toward the mature end cells. Because commitment is gradual, there is a continuous spectrum of multipotential stem cells. Thus, some of them may be able to respond to inducers of one sort or another. In terms of self-renewal, multipotential stem cell populations continually occupy each potential for proliferation at any given time and therefore respond to the requirement for each cell type. Some daughter cells will differentiate into the next stage. The continual development of stem cells may not be diverted entirely toward one cell type, even in the presence of differentiation factors for that type. Because stem cells divide as they respond, some cells are still able to progress to the next stage of commitment.

### Antigen-Dependent Stage of Lymphopoiesis – Part 2

The second part of this model deals with the Ag-dependent stage, after receptors are expressed on the surface of lymphocytes. There are two main lineages of lymphocytes: T-cells and B-cells. T-cells can mature into CD8<sup>+</sup> cytotoxic T-cells and CD4<sup>+</sup> helper T-cells. Based on their function and the spectrum of cytokines produced, helper T-cells can be divided into Th<sub>1</sub> and Th<sub>2</sub> subpopulations. The main functions of CD4<sup>+</sup> T-cells are to recognize cell-bound antigen and to communicate with and help cytotoxic T-cells and B-cells to perform their duties as effector cells. Both lineages generate memory cells. How and when lymphoid cells are committed to differentiate into effector cells or into memory cells remain a mystery.

## V. DIAGRAMS TO EXPLAIN THIS MODEL

Figure 51.1 is a simple diagram to explain this model. HSCs are multipotential stem cells derived from the mesoderm. Originally they are descended from common stem cells (null, or 0, cells), such as fertilized eggs, and from ESCs. The cells diagonally to the right (Fig. 51.1) represent cells committed to hematopoietic lineages, which gradually lose their multipotentiality during embryogenesis. This concept is expressed with numbers (5, 4, 3, and 2) inside the progeni-

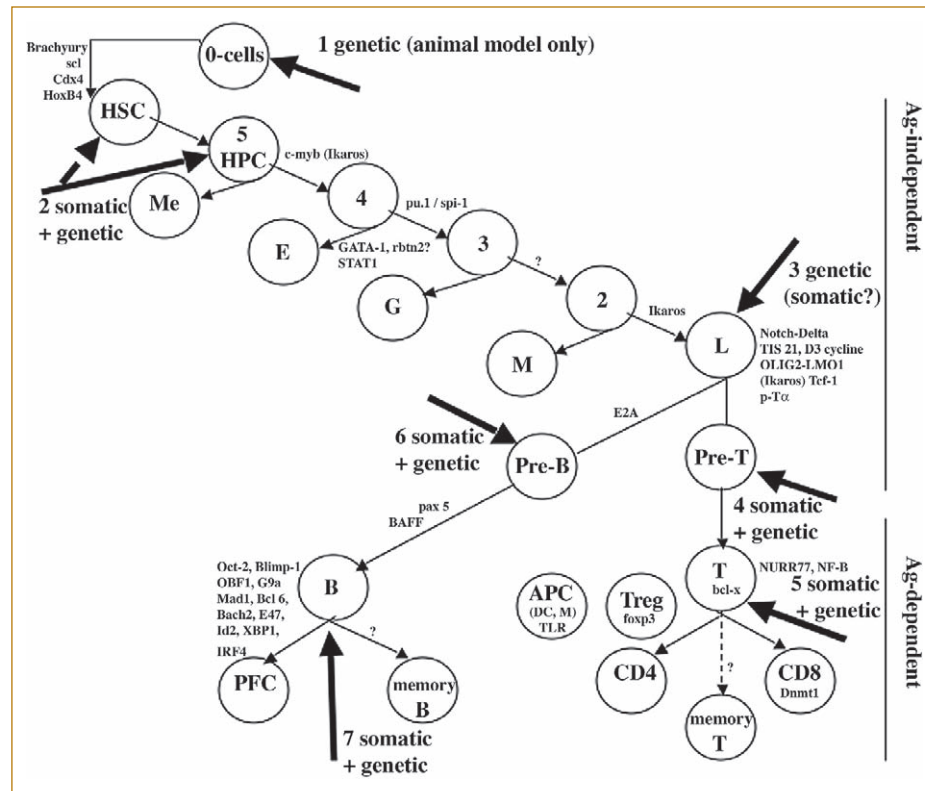

tor cells on the diagonal. For example, HSCs (noncycling) enter the proliferating stage to become the hematopoietic progenitor cells (HPCs, cycling). The number 5 cell, for instance, means that the HPCs at this stage have the potential to differentiate into five different types of precursor cells.

The committed, monopotential precursor cells then differentiate toward mature end cells, such as megakaryocytes (Me), erythrocytes (E), neutrophils/granulocytes (G), monocytes (M), and lymphocytes (L). Lymphoid precursor cells then differentiate into monopotential precursors for B- and T-cells. After expression of Ag receptors on the cell surface and on encountering Ag, B-cells differentiate into plaque-forming cells (PFCs, i.e., plasma cells) or memory B-cells. T-cells become CD8<sup>+</sup> or CD4<sup>+</sup> after thymic education, maturation, and negative and positive selection. Memory T-cells are generated later during differentiation. (Fig. 51.4 shows the markers and events that occur during the development of pre-T-cells — the process of maturation, education, and apoptosis of mature CD4<sup>+</sup> or CD8<sup>+</sup> T-cells from CD4<sup>+</sup>8<sup>+</sup> T-cells, also shown in figures derived from Kisielow and von Boehmer, 1995; Rodewald and Fehling, 1998, cited in Chen, 2000.) Genes encoding transcription factors and other important genes known to be expressed specifically in lymphopoiesis and that affect function, i.e., loss of function (knockout, down) or gain of function (ectopic expression by transducing with retroviral vectors containing transgene of interests), include *Brachyury*; *scl*; *Cdx4*; *HoxB4*; *c-myb*; *GATA1*, -2, -3; *rbtn2*; *pu.1/spi-1*; *Ikaros*; *TIS21*; *D3 cycline*; *Notch-Delta*; *Tcf1*; *E2A*, *pax5*; *BAFF*; *Oct-2*, *Blimp1*; *OBF1*; *G9a*; *Mad1*, *Bcl6*; *Bach2*; *E47*; *Id2*, *XBP1*; *IRF4*; *pTalpha*; *bcl-x*; *Dnmt1*; *foxp3*; *TLR*; *p53*, and more (Matthias and Rolink, 2005).

## VI. SOME COMMENTS ON THIS MODEL

Very little is known about how totipotent and pluripotent stem cells differentiate into ectoderm, mesoderm, and endoderm or how mesoderm differentiates into hematopoietic lineages. These are the central issues of embryogenesis, and this part of the model is intentionally very sketchy. Why and when multipotential, lineage-specific stem cells divide asymmetrically or progress to the next stage of commitment are unknown. The underlying rules may be stochastic or inductive. But the progression of the stage of commitment is more likely due to the turning on and off of genes encoding transcription factors.

Brown and coworkers originally formulated their model based on the data from the differentiation pattern of several myeloid cell lines. The scheme of the development of lymphoid lineages was purely hypothetical in the original model, and the development of mature lymphoid cells (in Part 2) was not included. It was proposed that precursor B-cells become committed before precursor T-cells. I have modified this step to the precommitment to lymphoid precursor cells. Also, I have changed the commitment of

**FIG. 51.1.** Proposed sequence of cell commitment during lymphopoiesis and stages of hematopoiesis and lymphopoiesis at which somatic and/or genetic engineering of lymphocytes and their precursor cells might be feasible. Solid block arrows point to the cell stages that might be targeted. The first part of the theory is the sequential commitment model of hematopoiesis of Brown *et al.* (1985, 1988), modified to include the pattern of expression of transcription factors. The cells depicted diagonally to the right represent hematopoietic stem cells (HSCs) committed to multipotential precursor cells or hematopoietic progenitor cells (HPCs), which gradually lose pluripotency, as expressed by the numbers 5, 4, 3, and 2 inside the stem cells. Number 5, for example, means that the HPCs at this stage have the potential to differentiate into five different types of precursor cells. The committed monopotent precursor cells can then differentiate toward mature end cells, such as megakaryocytes (Me), erythrocytes (E), neutrophils/granulocytes (G), monocytes (M), and finally lymphocytes (L). HSCs are derived from very primitive stem cells (null cells, or 0 cells), such as fertilized eggs and/or embryonic stem cells (ESCs). In the second part of the theory, lymphoid precursor cells differentiate into monopotent precursor B-cells (B) and monopotent precursor T-cells (T). After the expression of cell surface receptors and on encountering antigen (Ag), B-cells can differentiate to plaque-forming cells (PFCs) or memory B-cells. T-cells can become CD8<sup>+</sup> or CD4<sup>+</sup> cells after education and maturation in the thymus. Memory T-cells can be generated at a certain stage of differentiation. Regulatory T-cells are rediscovered and APCs (antigen processing cells), including dendritic cells and macrophage, seem to play a role in directing peptide-antigen recognition and activation of Th<sub>1</sub> vs Th<sub>2</sub>. Lipid antigen is directed to TCR via the CD1 molecule pathway. The transcription factors are expressed and are known to affect differentiation. The data come mostly from phenotypic expression in loss/gain of function approaches: Brachyury, scl, c-myb, GATA-1, rbtn2, pu.1/spi-1, Ikaros, Tcf-1, E2A, pax 5, Oct-2, Blimp-1, pTalpha, bcl-x, and p53 (refs. cited in Chen, 2000). Recent additions of the orchestra are Cdx4, HoxB4, STAT1 (Halupa *et al.*, 2005), Notch-Delta, TIS21, D3 cycline, foxp3, BAFF, OBF1, G9a, Mad1, Bcl6, Bach2, E47, Id2, XBP1, IRF4, and TLR (refs. cited in the text).

lymphoid precursor cells to occurring after the myeloid precursor cells. However, the committed lymphoid precursor cells should still be viewed as hypothetical, because there are many examples supporting the common lineage development of B-cells and myeloid cells and not of precursor T-cells. Committed lymphoid precursor cells are not clearly identified and isolated (details in Stage 3, later).

There is ambiguity in the original model. For example, the issue of the timing of each point of decision was not addressed. The original hypothesis implied that stem cells that do not receive the appropriate signals would proceed “spontaneously” to the next stage in the differentiation

sequence. Based on published data and on observations on the abortive development of lymphoid cells from blood islands derived from embryoid bodies (EBs) (Chen *et al.*, 1997; Chen, 2000) and on the essential requirement of cytokines to maintain and to propagate stem cells derived from transgenic fetal liver, I tend not to be in favor of spontaneous progression; appropriate inductive signals for the transcriptional activation of lineage-committed genes are stringently required. Moreover, because programmed cell death plays an important role in the fate of cells during embryogenesis, I have included apoptosis as another important factor. This model has gained support from the phenotypes of mice in which genes encoding

transcription factors have been deleted by knockout, knockdown, the so-called loss-of-function approach, and from the phenotype of cells in which transgenes are transduced using retroviral vectors, the so-called gain-of-function approaches. Transcription factors controlling the sequential commitment of HSCs have been summarized (Chen, 2000).

## VII. CRITERIA FOR ENGINEERING DEVELOPMENTAL STAGES OF LYMPHOPOIESIS

I attempt to explore the feasibility of engineering lymphoid cells and their stem cells at several defined stages of differentiation. The criteria for deciding on feasibility are (1) intrinsic self-renewal of HSCs, HPCs, and more differentiated cells; (2) the availability of cell surface markers for identification and purification; (3) the supply of recombinant growth factors and appropriate stroma cells; (4) the existence of favorable cell culture conditions that promote growth instead of differentiation; (5) the possibility of educating lymphocytes to become antigen-specific memory cells; and (6) the possibility of introducing, either genetically or somatically, genes of interest along with inducible promoter and regulatory sequences. Technical advances make the engineering of HSCs, HPCs, and lymphoid cells attractive for further manipulation, such as introducing new genes or reprogramming cells.

## VIII. STAGES OF LYMPHOPOIESIS FOR ENGINEERING

Figure 51.1 shows a schematic diagram of the stages at which lymphoid cells and lymphoid precursor cells might be engineered. The stages are next discussed individually.

### Stage 1: 0 Cells

Null (0) cells include the fertilized eggs, which are totipotent, and the blastocyst-derived embryonic stem (ES) cell lines, which are pluripotent. Mouse ES cell lines of different strain origin have been available for a long time, and they possess the property of differentiation into different somatic lineages *in vitro* and *in vivo*, homologous recombination, and germ-line transmission through the crossing and breeding of progeny. ES cells from many animal species are also available. Establishment of human ES-like cell lines has been reported since 1998, and now many IVF units can derive such cell lines. Several lineage-committed cells, such as from bone and cartilage, have been shown to be obtainable through differentiation *in vitro*. However, strictly speaking, the only way to prove that an hES cell line is truly pluripotent is to demonstrate germ-line transmission in human beings — a task that should not even be considered. Similarly, genetic and cellular engineering at this level should be limited to study *in vitro*. ES cells are stem cell lines that divide symmetrically. Unlike lineage-committed stem

cells, which are rare, ES cells are almost an exception, being readily available in abundance. mES cells can proliferate without differentiation if feeder cells and/or cytokines such as LIF (leukemia inhibitory factor) are provided, while hES cell lines established so far are feeder cell dependent, and LIF has no supportive effect. They can be induced to differentiate by removing the feeder cells (and cytokines). A few surface molecules are available for characterizing ES cells. Antibodies against various components that have been used to characterize such cells, such as antibody against stage-specific embryonic antigen-1 (SSEA-1), enable one to distinguish undifferentiated from differentiated mES cells. mES cells are SSEA1<sup>+</sup>, SSEA3<sup>+</sup>, SSEA4<sup>+</sup>, TRA-1-60<sup>+</sup>, TRA-1-81<sup>+</sup>, Oct4<sup>+</sup>, Oct6<sup>+</sup>, AP (alkaline phosphatase)<sup>+</sup>, telomerase<sup>+</sup>; hES cells are SSEA1<sup>−</sup>, SSEA3<sup>−</sup>, SSEA4<sup>−</sup>, TRA-1-60<sup>−</sup>, TRA-1-81<sup>−</sup>, Oct4<sup>−</sup>, AP<sup>−</sup>, telomerase<sup>−</sup>.

In recent years, stem cell genomics, or the systems biology approach to stem cells, has become popular. It considers the complex nature of cells and aims at a comprehensive understanding of stem cell mechanisms. Gene expression profiles of different stem cell types are being determined using DNA microarrays. These molecular signatures are stored and available in the stem cell database and allow a comparison of different stem cell types. On the basis of the obtained molecular signature, candidate genes, such as transcription factors, are subjected to the loss-of-function approach by knocked-out, knocked-in, or knocked-down by RNAi, and the effects on the expression of downstream genes are determined with DNA microarrays. In this way, gene regulatory networks could be identified rapidly.

For example, this approach is used to identify gene regulatory networks implicated in the self-renewal and differentiation of mES cells. Based on a microarray time course study of retinoic acid-induced ES cell differentiation, 169 genes that are down-regulated in the course of differentiation were found, and 40 of them were further investigated. ES cell cultures infected with lentiviral vectors containing the EGFP gene in addition to one of these 40 genes (RNAi knockdown or overexpression) were investigated in a competition assay, where respective infected cells were mixed with noninfected cells. In this way, higher or lower proliferation rates of the infected cells could be determined based on measured EGFP fluorescence. Changes in ES cell number could be due to a function of the respective gene in cell-cycle progression, cell survival, or prevention of lineage-specific differentiation. Downstream effects of changes of gene expression were determined with DNA microarrays. Such an approach also applies to the study of other cells, such as hES cells and hEC cells (Sperger *et al.*, 2003), HSCs (Ivanova *et al.*, 2002), pre-B-cells (Hoffmann *et al.*, 2003), and T-reg-cells (Bruder *et al.*, 2004). In addition to microarray studies for stem cells, the extent of posttranscriptional modifications within the stem cell transcription is under way. Thousands of genes expressed in HSCs and ES cells

undergo alternative splicing. Using combined computational and experimental analyses, the frequency of alternative splicing has been found to be especially high in tissue-specific genes, as compared to ubiquitous genes. Negative regulation of constitutively active splicing sites can be a prevalent mode for generation of splicing variants, and alternative splicing is generally not conserved between orthologous genes in human and mouse (Pritsker *et al.*, 2005; Lemischka and Pritsker, 2006).

Many genes encoding lymphoid-specific functions have been knocked out, and more studies are under way to develop specific deletions or replacements of genes by various techniques (Fig. 51.1). Vectors with inducible promoters are being used to introduce genes in a controllable, tissue-specific manner.

### Growth Requirement for Differentiation of ES Cells to Lymphoid Cells

Under appropriate conditions, ES cells can differentiate *in vitro*. Many different culture systems are available for studying the development of lineage commitment. Because ES cells are pluripotent, optimal culture conditions would enable the formation of mature cells and tissues and even of organs in well-organized three-dimensional structures *in vitro*. That is, one should be able to generate an artificial fetus in culture without any external cells or other factors. In fact, of course, organogenesis from ES cell culture is but a dream. Nevertheless, with the culture conditions and system that we have developed, mature and embryonic cells in some form of tissuelike organization, though never organs, of certain orderly structures (gutlike, epidermallike, and thymuslike structures), can be observed.

Many genes have been identified that play important roles in the differentiation of ES cell to mesoderm and then to derivatives such as HSCs (see figure legends). Recently, more genes have been identified; for example, mMix (a homeobox gene Mix-like) is reported to play a critical role in gastrulation and may function early in the recruitment and/or expansion of mesodermal progenitors to the hemangioblastic and hematopoietic lineages (Willey *et al.*, 2006). Hematopoietic defects have been identified in differentiating mMix<sup>-/-</sup> ES cells. Conditional induction of mMix in ES-derived EBs results in the early activation of mesodermal markers prior to expression of Brachyury/T and acceleration of the mesodermal developmental program. Increased numbers of mesodermal cells, hemangioblastic cells, and HSCs form in response to premature activation of mMix. Differentiation to embryonic and mature blood cells proceeds normally and without an apparent bias in the representation of different hematopoietic cell fates.

Many researchers have attempted but failed to study the differentiation of lymphopoietic precursor cells obtained from mES cells. Many observe the development of yolk sac blood islands in culture; these presumably contain HSCs. But only myeloid cells could be produced in the culture

systems reported. Only a few systems allow the generation of lymphoid precursor cells, mostly B-cells but also T- and B-cells, in a quantity sufficient for further manipulation (Chen *et al.*, 1997; Chen, 2000).

The reasons for these variations are unclear. It is partially due to the origin and pluripotentiality, hence the fragility and variability, of ES cells but partially due to experimental manipulations, different culture conditions, (Chen *et al.*, 1997, also recently reviewed by Dang *et al.*, 2002), and the transient expression of genes relevant to the developmental stage of hemato-lymphopoiesis from mesoderm equivalent at the yolk sac stage. HoxB4 (see later) is an example of such genes of recent discovery. Even in the hands of a single researcher, the potential of lymphopoiesis from the same ES cell lines varies greatly among different experiments, and why this is so remains a mystery. The culture conditions vary, depending on which lineages are chosen for study. For example, methylcellulose culture is preferred for myeloid lineages but is inferior for lymphoid lineages. Several culture conditions that favor the differentiation of ES cells to lymphoid lineages are available.

Through the work of many groups, it has become clear that lymphoid precursor cells can be obtained from ESCs in culture. However, the development of mature B plasma cells and mature T-cells requires a two-step procedure — a two-step culture procedure for plasma cells, and culture and animal implantation for mature B- and T-cells. When chimeric bone marrow cells from embryoid body–implanted nude mice, which contain cells of ESC origin, were injected into the host mice, the bone marrow cells were shown to repopulate the primary and secondary lymphoid organs, i.e., bone marrow, spleen, and lymph nodes. The data indicate that HSCs and HPCs of ESC origin can be transferred. However, when injecting into the host animal, such as lethally irradiated adult mice instead of unirradiated nude mice, dissociated cells from blood island of the EB, instead of the whole EB, killed the mice when intravenous injection was performed, and failed to repopulate the host immune system or to achieve a stable engraftment when intraperitoneal injection was performed (reviewed in Chen *et al.*, 1997).

The recent work on the expression of (transcriptional) molecules such as HoxB4, Cdx4 (of Cdx-Hox pathway), and especially the transduction of transgenic expression under the inducible tet-promoter using retroviral vector, has been shown to understand the mechanism and pathway. HoxB4 is a homeodomain-containing transcription factor with diverse roles in embryonic development and the regulation of adult stem cells. This gene has a double life and can act in opposite ways when expressed by different cells, promoting the proliferation of stem cells while activating the apoptotic pathway in some embryonic structures. It is implicated in self-renewal of definitive HSCs, transiently expressed in blood developmental stages somewhere between the yolk sac stage and the fetal body stage and also expressed in human cervical carcinoma (Lopez *et al.*, 2006). Persistent

overexpression of HoxB4, however, inhibits the development of blood lineage.

It was examined to show its effect on hemopoiesis using a variety of tools, including retroviral transgenic expression (Sauvageau *et al.*, 1995; Helgason *et al.*, 1996; Antonchuk *et al.*, 2002; Kyba *et al.*, 2002). Expression of HoxB4 in primitive progenitors, and when combined with culture on stromal cells, induces a switch to the definitive HSC phenotype. These progenitors engraft lethally irradiated adult mice and contribute to hematopoiesis in primary and secondary hosts. Thus, HoxB4 expression promotes the transition from primitive cells to become HSCs. Overexpression, a high level of expression, of HoxB4, however, is shown to perturb the differentiation and to predispose the manipulated cells to leukemogenesis. HoxB4 may affect cell growth in a dose-dependent manner and may disturb the differentiation into lymphopoiesis (Will *et al.*, 2006; Pilat *et al.*, 2005; Abramovich *et al.*, 2005).

This approach involving the manipulation of essential genes has overcome, partially, the problems of variability of the development of hematopoietic cells from mesoderm-derived cells, such as yolk sac cells and EBs, and increased engraftment into irradiated adult mice (Wang *et al.*, 2005). Combining HoxB4 gain of function and Cdx4 gain of function has been shown to increase the multilineage hematopoietic, including lymphoid, engraftment of lethally irradiated adult mice.

Others that have been tried are: mMix (see earlier, Willey *et al.*, 2006); Stat 5, a signal transducer under similar inducible conditions to express in mES-derived HSC and to grow similarly on OP9 stroma cells, shown to increase the induction of preferable myeloid, rather than lymphoid, differentiation (Kyba *et al.*, 2003); BCR/ABL, a chronic myeloid leukemia-associated oncoprotein, is shown to transform a subset of HSC between erythro- and lymphoid-myeloid lineages (Daley, 2003).

The combined *in vitro* and *in vivo* culture system described earlier using nude mice as the hosts can also be employed to study thymic stroma as well as well-organized, highly differentiated cells of many other lineages, including gut epithelia, skin with hair follicles, bone, muscle, neurons, and glia. One essential requirement for applying this combined system with success is that the cells differentiate first in culture, until the EB developed before the subcutaneous implantation. Otherwise, tumors may grow, due to the expression of the acylated dimeric iLRP (immature 32–44 kDa laminin receptor protein) and other, still-to-be-identified oncofetal antigen (OFA) positive in early to mid-gestation (Rohrer *et al.*, 2001). The development of endogenic thymic epithelial cells as well as stroma cells inside the ES-embryonic bodies also explain partially the findings of an efficient development of T-cells in the absence of exogenous stroma cells.

Stroma cell line RP.0.10 is able to support both T- and B-lymphoid precursor cells derived from ESCs in some labs,

but this has not been reproducible elsewhere. Stroma cell lines OP9 and S17 were originally reported to support B-precursor cells and myeloid but not T-precursor cells derived from ESCs. Many other stroma cell lines do not support the differentiation of ESCs to lymphoid precursor cells. The S17 stroma cell line was compared to many stroma cell lines for the production of cytokines and stroma function, i.e., the stem cell support function (ref. cited in Chen, 2000) (see also later, Stage 2); there were no correlations in the assays. Thus a yet-to-be-identified extracellular matrix molecule of S17 cell lineage may play a role in supporting the function of HPCs.

Recently, with the insertion of genes involved in Notch-Delta signaling pathways, it was shown that the OP9-derived cell line, OP9-DL1 (Delta-like 1), increases efficient T-cells, which appeared from sources such as fetal liver (Taghon *et al.*, 2005), human cord blood (La Motte-Mohs *et al.*, 2005), and ES cells (de Pooter *et al.*, 2005). The study using switch cultures shows that while necessary to induce and sustain T-cell development, Notch/Delta signaling is not sufficient for T-lineage specification and commitment but, instead, can be permissive for the maintenance and proliferation of uncommitted progenitors that are omitted in binary-choice models. Moreover, it was demonstrated that a three-dimensional structure to allow the interaction of precursor-supporting cells plays an essential role for it to function well (see also later, Stage 4).

Other candidate molecules and cells that may support the lymphopoiesis include the following: dlk, an epidermal growth factor-like molecule of 66 kDa in stroma cell lines was reported to influence the requirement for IL (interleukin)-7 in supporting mouse pre-B lymphopoiesis, and dlk is suggested to play an important role in the bone marrow HPC microenvironment. Another high-molecular-weight CD166 (HCA/ALCAM) glycoprotein was shown to express in human HPCs as well as stroma cells. This molecule is involved in adhesive interaction between HPCs and stroma cells in the most primary blood-forming organs.

Rethinking the seemingly conflicting results and the inconsistent report of differentiation of ES cells to lymphocytes, I wonder if culturing ES-derived lymphoid progenitor cells on stroma cell lines derived from the most primitive stroma environment from the fetus (such as paraaortic cells) may be a better choice to obtain consistent results, rather than using the existing stroma cell lines. Indeed, stroma cell lines from such a source have been derived.

The field of hESCs (human embryonic stem cells), only in its infancy, represents a theoretically inexhaustible source of precursor cells that could be differentiated into any cell type to treat degenerative, malignant, or genetic diseases or injury due to inflammation, infection, and trauma. This pluripotent, endlessly dividing cell has been hailed as a possible means of treating various diseases. hESCs are also an invaluable research tool to study development, both normal and abnormal, and can serve as a platform to develop and test

new therapies. They are also a potential source of HSCs for therapeutic transplantation and can provide a model for human hematopoiesis. The first stable hES cell line was reported in 1998 (Thomson *et al.*). Eight years later, many centers could establish hES cell lines. The current goal is to establish clinical grade hES cell lines for potential therapeutic purposes. At least two IND (introducing new drug) have been submitted for clinical trials, such as treating spinal cord injury repair. None of these studies is ready for treating blood disorders yet. The attempt to differentiate hESCs *in vitro* to HSCs has been reported (Kaufman *et al.*, 2001; Vodyanki *et al.*, 2005; Wang *et al.*, 2005; Zambidis *et al.*, 2005; Narayan *et al.*, 2006; Bowles *et al.*, 2006).

From such studies, hES cells are shown to differentiate to HSCs, using various protocols and different supportive stroma cell lines, with or without cytokines. It seems that the differentiation into mesoderm-derived lineages and then to mesodermal-hematoendothelial (MHE) lineage can occur, resembling human yolk sac development. The cellular and molecular kinetics of the stepwise differentiation of hESCs to primitive and definitive erythromyelopoiesis from hEBs in serum-free clonogenic assays have been demonstrated (Zambidis *et al.*, 2005). Hematopoiesis initiates from CD45<sup>+</sup> hEB cells, with the emergence of MHE colonies. They can generate endothelium and form organized, yolk sac-like structures that secondarily generate multipotent primitive HSPCs, erythroblasts, and CD13<sup>+</sup>CD45<sup>+</sup> macrophages. A first wave of hematopoiesis follows MHE colony emergence and is predominated by primitive erythropoiesis. A second wave of a definitive type of colonies of erythroid, GM, and multilineage CFCs follows. These stages of hematopoiesis proceed spontaneously from hEB-derived cells without requirement for supplemental growth factors during hEB differentiation. Gene expression analysis revealed that initiation of hematopoiesis correlated with increased levels of SCL/TAL1, GATA1, GATA2, CD34, CD31, and Cdx4. These data indicate that the earliest events of embryonic and definitive hematopoiesis can be differentiated from hESCs *in vitro*.

However, differentiating hEBs further into HSCs, and lymphohematopoietic lineages becomes variable and unpredictable, according to several reports. In one report, when cocultured with S17, a mouse stroma cell line, or C166, a yolk sac endothelial cell line, and in the presence of FCS, without cytokines, hES cell-derived HSCs are shown to be CD34<sup>+</sup>TAL1<sup>+</sup>LMO2<sup>+</sup>GATA2<sup>+</sup>. When cultured on semisolid media with growth factors, these HSCs form characteristic erythroid, myeloid, and megakaryocyte colonies. More terminally differentiated hematopoietic cells derived from hES under these conditions also express normal surface antigens of the corresponding lineages: glycophorin A<sup>+</sup>, CD15<sup>+</sup>, and CD41<sup>+</sup>. No lymphoid lineage was generated using such stroma cells and culture conditions. When cocultured with OP9, a mouse stroma cell, it is possible to obtain up to 20% of CD34<sup>+</sup> cells and isolate up to 10(7) CD34<sup>+</sup> cells with more than 95% purity from a similar number of initially plated

hES cells after eight to nine days of culture. The hES-derived CD34<sup>+</sup> cells were highly enriched with CFC (colony-forming cells), expressing GATA1<sup>+</sup> GATA2<sup>+</sup> SCL/TAL1<sup>+</sup> Flk1<sup>+</sup>, and retained clonogenic potential after *in vitro* expansion. Such HSCs are shown to be CD34<sup>+</sup>CD90<sup>+</sup>CD117<sup>+</sup>CD164<sup>+</sup> CD38<sup>−</sup>ADH (aldehyde dehydrogenase)<sup>+</sup> rhodamine 123<sup>flux+</sup>. When cocultured with hES-derived CD34<sup>+</sup> cells on MS-5 stroma cells in the presence of SCF, Flt3-L, IL-7, and IL-3, they differentiated into B lymphoid cells, natural killer cells, and myeloid (macrophages and granulocytes) lineages. No T lymphoid lineage could be demonstrated to generate under such conditions. The OP9 DL1 cell line (see earlier) was not applied in this study. The derived cells can differentiate into other cells when implanted into fetal sheep intraperitoneally and differentiated in primary and secondary hosts (Narayan *et al.*, 2006).

The transit expression of transcription factor HoxB4 (see earlier) appears to play a role in determining cells to become lymphoid cells in the mouse system and would explain the occasional determination of precursor cells to commit to lymphoid lineages. It implies right away that it can apply to study the lymphohemopoiesis in the human system. Indeed, a recent report (Bowles *et al.*, 2006) has provided data on such an attempt. Culture of hES cells on mouse feeder cells or in cell-free culture conditions results in low levels of differentiated HPCs. Transgenic stable HoxB4-hESC clones were generated by the lipofectamin transfection method. *In vitro* differentiation of hESCs, as EBs, in serum containing medium without cytokines led to the sequential expansion of erythroid, myeloid, and monocytic progenitors from day 10 of culture. These cells retained the capacity to develop into formed blood elements during culture. Overexpression of HoxB4 considerably augments the development of three myeloid lineages of hESCs; however, no lymphoid progeny were reported. Since this approach is very different from the transduction using mouse retroviral vector and involves the human cell system, it is too early to draw any conclusions at this stage regarding the role of HoxB4 in human lymphohemopoiesis.

Theoretically, lentiviral vector introducing HoxB4 under a tet-on system should be a comparable approach for further study. However, another report does not support this notion or show a functional role of HoxB4 in HSCs in their combined *in vitro* and *in vivo* system, using SCID mice (Wang *et al.*, 2005). It is interesting that hES-derived HSCs failed to reconstitute i.v. transplanted host because of cellular aggregation causing fatal emboli formation, which is similar to our attempt using mEBs-derived cells. Direct femoral injection allowed host survival and resulted in multilineage hematopoietic repopulation. However, hES-derived HSCs had limited proliferative and migratory capacity as compared with somatic HSCs, which correlated with a distinct gene expression pattern of hESC-derived HSCs that included HoxA and HoxB gene clusters. Transduction of HoxB4 had no effect on the repopulating capacity of hES-derived cells.

A yet-to-be-identified molecular program is postulated to contribute to the atypical behavior of hES-derived cells *in vivo*.

Thus, conflicting reports continue to surface, giving the impression that the differentiation into lymphohematopoiesis seems to be, if not more rare, then as rare and as variable as the *in vitro* differentiation system using mES cells. The questions of the variability among different hES cell lines and clones, similar to the observation using mES cells, are also reported. The derived somatic tissue-committed stem precursor cells remain rare. How to study individual gene expression using hES cells and its relationship with the group of genes and the final outcome of the cell fate is a challenge and will require more time in the future. Combining multiple genes, such as mMix, Cdx4, and HoxB4, with a gain-of-function approach might be the next possibility to attempting to increase the lymphohematopoiesis derived from hES cells (also, with Bowles, personal communication).

## Stage 2: HSCs and HPCs

The terms *hematopoietic* stem cells, *progenitor* cells, and *precursor* cells are used loosely in the literature. Hematopoietic stem cells and hematopoietic progenitor cells are defined as two populations of stem cells sharing similar surface markers. HSCs are rather quiescent, noncycling stem cells, whereas HPCs are cycling cells. In mice, c-kit<sup>+</sup>, thy-1<sup>low</sup>, lin<sup>-</sup>, and sca1<sup>+</sup> bone marrow cells are defined as HSCs or HPCs. HSCs and HPCs in bone marrow are heterogeneous in size and in self-renewal capacity. Moreover, they have finite life spans. In human bone marrow, CD34<sup>+</sup>HLA<sup>-</sup>lin<sup>-</sup>thy-1<sup>low</sup>rhodamine123<sup>low</sup> stem cells are generally defined as HSCs and HPCs. However, CD34 is also expressed in other lineages, such as vascular endothelial cells and muscle precursor cells. It is well established that mouse HSCs and HPCs can be isolated, cultured, and transduced by retroviruses and used to repopulate animal hosts. In addition to bone marrow, they can be isolated from fetal liver, cord blood, fetal blood, yolk sac, and paraaortic splanchnopleura.

## Do HSCs and HPCs Self-Renew?

The self-renewal of HSCs and HPCs was carefully examined (ref. cited in Chen, 2000). By transferring bone marrow stem cells from one host to the other, it was found that the pool of donor bone marrow stem cells was smaller on transfer, and it was concluded that self-renewal is limited for somatic bone marrow stem cells. However, the results could be due to a dilution effect of the donor stem cells, if a certain absolute number of stem cells was required for the successful implantation of donor stem cells in the bone marrow. Using fluorescence *in situ* hybridization (FISH) and telomerase assays, it was shown that telomere DNA length predicts the age and replication capacity of human fibroblasts.

The telomere DNA length has been correlated with the replication potential of HSCs and HPCs. In human CD34<sup>+</sup>, CD71<sup>low</sup>, and CD45RA<sup>low</sup> bone marrow stem cells, the length of telomeric DNA in HSCs and HPCs is correlated with the age of the donor. The stem cells in adults have shorter telomere than found in fetal cells, but both have the same telomerase activity. When the HPCs were expanded with cytokines without the support of stroma cells, there was a loss of telomeric DNA in culture. The loss of telomeric DNA in HSCs and HPCs from older people and cultured stem cells was interpreted to mean that their replication potential is finite. An alternative interpretation would be that the culture conditions that allow stem cells to grow in the presence of cytokines may not favor the maintenance of telomerase activity and hence not the self-renewal of HSCs and HPCs.

Many culture systems for studying the biology of mouse HSCs and HPCs are available. Many mouse stroma cell lines support the growth of HPCs. Studies on human stem cells use mouse stroma cell lines, such as S17 and AFTO24 (Nolta *et al.*, 2002), among many others, or mixed primary stroma populations, recently called MSCs (mesenchymal stem cells), isolated from human bone marrow or other sources, to support purified HSCs and HPCs or unseparated bone marrow cells. The establishment of heterogeneous human stroma cell lines with the help of a plasmid-containing SV40 T antigen under the control of an inducible metallothionein promoter has been reported, but their ability to support lymphopoiesis could not be demonstrated. Mixed human stroma cells, or MSCs, and cell lines that support human long-term culture-initiating cells also exist. However, these human stroma cell lines could not be shown to support the development of human lymphocytes from bone marrow stem cells.

Recently, MSCs have become a promising field, and many clinical trials are under way. The expansion of human MSCs in culture presents a challenge. They proliferate poorly in medium supplemented with human serum, and they require the presence of selective lots of FCS. A recent report has indicated that prolonging the culture of MSCs runs the risk of becoming tumor cells (Rubio *et al.*, 2005).

Major problems in this field are the variability of culture conditions, the efficiency of differentiation of the cultured cells to lymphoid lineages, and the poor reproducibility in the hands of different investigators. Also contributing to problems is the failure to report specific reagents and ingredients used as well as undescribed procedures, stroma cell conditions, batches of serum, and growth factors required in each system. Of course, the intrinsic multipotentiality of HSCs and HPCs also contributes significantly to variability. Many have claimed that a cocktail of cytokines alone could promote the differentiation of myeloid lineages from HSCs and HPCs in mouse and human (ref. cited in Chen, 2000) systems. A few have claimed the development of B-cells at various stages of maturation, but no mature T-cells could be

found in such culture conditions. The maintenance of long-term cultures of self-renewing stem cells with potency for lymphopoiesis, especially T lymphopoiesis, requires stroma cells, additional cytokines, a three-dimensional structure to support the precursor cell–stroma cell interaction (also see Stage 3), and other culture conditions yet to be defined. Several existing culture systems seem to be promising for expansion *ex vivo* and potential differentiation of human and mouse HSCs. Human-based supporting cell lines, such as an endothelial-like cell line, ECV304/T24, were used to generate split-function amphotropic packaging cell lines. This manipulated cell line, APEX, was used for transduction and for support of the growth of HSPs (Dando *et al.*, 2001). The development of supporting human cell lines for lymphopoiesis is essential for the production of large quantities of cultured cells for manipulation and reimplantation.

### Selected Examples of Clinical Applications of Human HSCs and HPCs

Using human HSCs and HPCs as the cell base for gene therapy is a complicated issue. In most clinical protocols, HPCs are transduced *ex vivo* with retroviral vectors and reimplanted into patients. One example undergoing clinical trial for a decade is the treatment of adenosine deaminase (ADA) deficiency. ADA deficiency exists in all cells examined. However, T-cells of these patients are selectively missing, causing a severe combined immunodeficiency (SCID) symptom. Despite decades of study, the mechanism by which the ADA defect causes specific deficiency of T-cells remains unknown. Possible mechanisms have been postulated, such as the apoptotic pathway of CD95 (Fas/apo-1)-induced cell death.

Patients suffering from ADA deficiency have been treated via two protocols: One trial uses autologous cord blood CD34<sup>+</sup> cells in ADA-deficient babies, and the combined cell and enzyme therapies seem to generate better immune function. Another trial uses ADA gene transfer therapy. Stem cells were expanded *in vitro* and transduced with retroviral vectors containing ADA genes. Several ADA-deficient children were subsequently followed up using the PCR (polymerase chain reaction) assay to assess the expression of circulating T-cells bearing the transduced ADA gene. Peripheral blood carrying the transduced ADA gene was shown to persist for seven months before disappearing. Bone marrow cells appeared later and became the major source of T-cells expressing the transduced ADA gene in the peripheral blood. Although initial reports of these studies claimed to be successful, careful evaluation of ADA gene therapy protocols shows that there is a major problem with the original protocols. During *ex vivo* expansion and manipulation for gene transfer, HPCs lose their capacity to proliferate in favor of differentiation and maturation. There was a need for repeated treatments of the same patient with retrovirus transduction, and continuous infusion of PEG (polyethylene glycol)-conjugated ADA enzyme. The differ-

ent results are due to the fact that very few mature, functional T-cells make enough enzyme to detoxify the serum in ADA patients. If stem cells are rare, small differences in technique and uncontrolled variables could make the difference between success and failure. Another, not mutually exclusive, interpretation of the lack of long-term reconstituting stem cells is that the cycling HPCs, transduced, are not the true stem cells. Human immunodeficiency virus (HIV)-based lentiviral vector has been shown to efficiently transfer foreign genes into postmitotic and noncycling cells, including HSCs. This vector and several package cell lines are still under development. Improved culture conditions for the growth and maintenance of human stem cells in large quantities are required. The establishment and use of reliable human stroma cell lines that could support the growth of lymphopoietic HPCs *in vitro* are urgently needed.

The current status of a phase 1/2 clinical trial of ADA-deficient SCID using gene-corrected HPCs has been reported. It has moved from the early trials of safety and feasibility to recent studies demonstrating efficacy and clinical benefit, an improved protocol running with four patients who have been enrolled for one to three years, without the infusion of PEG-ADA. It is a combination of low-dose chemotherapy with busulfan and a single transplantation with ADA-retroviral-transduced HPC. No patient has received a second dose of transduced HPC yet; no side effect has been reported to date, and they can return home and live normally. A protocol with IL-3 or IL-7 was included in another gene therapy clinical trial for ADA-SCID, resulting in long-term engraftment of stem/progenitor cells. The future direction of this clinical trial is to extend this improved protocol to treat more ADA patients (Aiuti *et al.*, 2002, 2003; Ficara *et al.*, 2004).

There is another recent study of the SCID-XI gene therapy clinical trials, in which HPCs are the target of murine leukemia virus (MLV)-derived retroviral vectors containing IL (interleukin) receptor gamma common chains. Immune function has been restored in 9 of 10 treated children with the transduction of gamma c gene transfer in CD34<sup>+</sup> cells. The distribution of both T-cell receptor (TCR) V beta family usage and TCR V beta CDR3 (complementarity-determining region 3) length revealed a broadly diversified T-cell repertoire. Further retroviral integration site analysis showed that insertion sites were shared by progenic T- and B-cells, granulocytes, monocytes, and the transduced CD34<sup>+</sup>. This finding demonstrates the initial transduction of very primitive multipotent progenitor cells with self-renewal capacity. These results provide evidence in the setting of a clinical trial that CD34<sup>+</sup> cells maintain both lymphomyeloid potential as well as self-renewal capacity after *ex vivo* manipulation (Schmidt *et al.*, 2005). However, due to the developed leukemia of two treated children (Hacein-Bey-Abina *et al.*, 2003; Wood *et al.*, 2006), the trial has been on hold for a period of time, and the research of this group has turned to focus on the basic biology of the oncogenicity

of the vector-related insertion site LMO2 of the affected T-cells and of using the Lmo2-TLL transgenic mice model. The integrations are found to reside within FRA11E, a common fragile site known to correlate with chromosomal break-points in tumors. The fragile sites attract a nonrandom number of MLV integrations. This explains the mechanism of two out of three leukemia cases. The other leukemia is currently attributed to the transplanted IL2RG gene (Wood *et al.*, 2006). This clinical trial is running continuously in the UK (Thrasher *et al.*, 2005), and clinical trials subsequently resumed in France and the United States based on case-by-case study (Christoph von Kalle, Fischer, 2005).

### Stage 3: Lymphoid Precursor Cells

The characterization of lymphoid lineage-committed precursor cells defined in terms of cell surface markers and functional assays of precursors and progenies is a challenge. One cell type that is described closest to the definition of lymphoid precursor cells is the CD4<sup>low</sup> precursor population isolated from adult thymus (ref. cited in Chen, 2000). Because this population of cells is restricted in its potential to differentiate into myeloid cells, it is preferentially committed to differentiate into T- and B-cells. These cells can also differentiate into thymic dendritic cells. The molecular markers of this population have not been well characterized. It would be interesting to see whether this population of cells can differentiate into myogenic cells, because Morgan and Partridge obtained differentiated myogenic cells from adult thymus. Thymus contains lymphoid and presumably mesenchymal precursor cells, recently called MSC (mesenchymal stem cells), which can develop into other lineages, such as bone, cartilage, and lung.

Little is known about the culture conditions for growing this population of cells. It is possible that stroma cell lines such as S17 could be used to expand the CD4<sup>low</sup> population of cells in culture, because it has been possible to use S17 and cytokines to maintain paraaortic splanchnopleural-derived precursor cells possessing the T-cell lineage potency in culture for some time (in Chen, 2000).

A lymphoid lineage-preferable transcriptional factor, Ikaros, was thought to be an important molecular marker of lymphoid precursor cells at this specific stage of development. Ikaros was subsequently shown to have multiple effects on HSCs, lymphoid cells, T precursor cells, and others.

Using the transgenic approach, it is possible to trace lymphopoiesis between common lymphoid precursor and alpha-beta T-cells. A transgenic mouse system is applied using pre-T-cell receptor alpha (pTalpha) promoter to drive the human CD25 (hCD25) surface marker as a reporter. It marked intra- and extrathymic lymphoid precursors but not myeloid cells. The extrathymic precursors were characterized as a common lymphoid precursor population (no. 1) expressing CD19<sup>-</sup>B220<sup>+</sup>Thy1<sup>+</sup>CD4<sup>+</sup> cells using clonogenic assays. The earliest intrathymic precursors were

CD4<sup>low</sup>CD8<sup>-</sup>CD25<sup>-</sup>CD44<sup>+</sup>c-Kit<sup>+</sup> cells and Notch-1 mRNA<sup>+</sup> (Gounari *et al.*, 2002).

By using the regulatory sequences from the gene encoding pre-T-cell receptor alpha to drive hCD25 reporter and to produce transgenic mice, the same group (Martin *et al.*, 2003) identified another common lymphoid precursor population (no. 2), which was B220<sup>+</sup>c-Kit<sup>-</sup>. In short-term culture, population no. 2 cells could be derived from the no. 1 subset and contained cells that in clonogenic assays were characterized as bipotent T- and B-precursors. Mature alpha-beta T-cells were produced when transgenic bone marrow cells were injected i.v.; thymocytes were cultured using a thymic organ culture system. The no. 2 subset may represent the most differentiated population with T-cell potential before commitment to the B-cell lineage.

The human counterpart of the CD4<sup>low</sup> population is unknown. Certain batches of FCS (fetal calf serum) might be supportive, because such batches are shown to support the growth and expansion of human MSC derived from cord blood. The expansion of CD34<sup>+</sup>, CD31<sup>+</sup> human bone marrow B-progenitor cells and partial differentiation to B-precursors in serum-free culture medium in the presence of mixed primary human stroma cells and IL-7 for a limited duration has been shown to be possible (ref. cited in Chen, 2000). A few such CD34<sup>+</sup> precursor cells could differentiate into natural killer (NK) cells and T-precursors when subjected to a secondary culture condition, with the thymic environment provided. It is not clear whether T-precursor cells are derived from HPCs or are the precommitted precursor cells migrating to bone marrow. The three-dimensional structure and the expression of Notch/Delta signaling of the thymic environment have been shown to play critical roles for supporting the differentiation of cells to the T-cell lineages (Mohtashami and Zuniga-Pflucker, 2006).

### Stage 4: Precursor T-Cells

Precursor T-cells are identified to be thy-1<sup>+</sup>, CD117<sup>low</sup>, DC3<sup>-</sup>, pTα<sup>+</sup> (ref. cited in Chen, 2000). They can be derived from fetal and adult blood. Using markers such as the CD25 and CD44, they can be classified into subpopulations, as shown in the two figures by Rodewald and Fehling (1998, cited in Chen, 2000), also in Fig. 4 of Hoffmann *et al.* (2003) and more recent reports. TIS21 (TPA-inducible sequence 21) is identified as an antiproliferative T-cell molecule of the BTG/TOB (B-cell translocation gene/transducer of ErbB-2) family member, also expressed in the quiescent T-precursors and in peripheral anergic and unstimulated T-cells. With the expression of TIS21, it is possible to divide such precursor T cells further into four populations. They are the quiescent CD44<sup>+</sup> CD25<sup>-</sup> TIS21<sup>+</sup> early cells and CD44<sup>-</sup> CD25<sup>+</sup> TIS21<sup>+</sup> cells prior to TCR beta selection. After the selection, the cells are the proliferating CD25<sup>+</sup> CD44<sup>+</sup> TIS21<sup>low</sup> precursor T-cells and CD25<sup>low</sup> CD44<sup>-</sup> TIS21<sup>low</sup> cells. By transgenic overexpression of TIS21 in precursor T-cells and HPC, it can inhibit the expansion of thymocytes (Konrad

and Zuniga-Pflucker, 2005). Thus, somatic and genetic manipulations would become easier with cloning and identifying such “quiescenting genes” and their ability to express at stage-specific matter.

Other genes of interests are the pre-T-cell receptor gene (preTCR) and the antiapoptotic A1 gene (BCL2A1) (Mandal *et al.*, 2005). PreTCR<sup>+</sup> cells are selected to survive and differentiate further, whereas preTCR<sup>-</sup> cells are selected to die. The mechanisms of preTCR-mediated survival are under investigation. The induction of the A1 gene will induce pre-T-cell survival by inhibiting activation of caspase-3. *In vitro* knockdown of A1 expression can compromise survival, even in the presence of a functional preTCR. However, the overexpression of preTCR-induced A1 can contribute to T-cell leukemia in both mice and humans. Whether it can contribute to the expansion of this population in culture is not known.

Another gene could be of interest: the cell-cycle control genes, such as the D3 cyclin of D type (D1, D2, D3) (Sicinska *et al.*, 2003). It could play a role in immature T-cell expansion. The D3 gene has been demonstrated to overexpress in several human lymphoid malignancies. The D3<sup>-/-</sup> mice failed to undergo normal expansion of immature T-cells and showed greatly reduced susceptibility to T-cell malignancies triggered by specific oncogenic pathways. Knockdown of cyclin D3 inhibited proliferation of human acute lymphoblastic leukemias that were of immature T-cell origin.

Both OLIG2 and LMO1 were overexpressed with large thymic tumor masses (Y. W. Lin *et al.*, 2005). Gene expression profiling of thymic tumors that developed in OLIG2-LMO1 mice revealed up-regulation of Notch1. Two genes considered to be downstream of Notch1 — Deltex1 (Dtx1) and preTCR- $\alpha$  — are also up-regulated. In three of six primary thymic tumors, mutations in the Notch1 heterodimerization, or proline-, glutamic acid-, serine-, and threonine-rich domains, are found. The established OLIG2-LMO1 leukemic cell line was suppressed by a gamma-secretase inhibitor, suggesting that Notch1 up-regulation is important for the proliferation of OLIG2-LMO1 leukemic cells.

T-lymphocytes are generated in the thymus, where developing thymocytes must accept one of two fates: They either differentiate or they die. These fates are determined by signals that originate from the TCR. CD4<sup>+</sup>CD8<sup>+</sup> thymocytes undergo one of three fates in the thymus: positive selection, negative selection (TCR-mediated apoptosis), or death by neglect. Only 5% of developing thymocytes are exported as mature T-cells. Negative selection of thymocytes that express TCRs with high affinity for self-peptide-MHC deletes potentially self-reactive thymocytes, generating a largely self-tolerant peripheral T-cell repertoire. Most negative selection is thought to occur in the thymic medulla, for this contains two types of specialized antigen-presenting cell—dendritic cells (DC) and thymic epithelial cells (TECs). Medullary TECs transcribe genes that are normally expressed in peripheral tissues. Negative selection can occur before or after, thus independent of, positive selection and

in thymocytes at all stages of development. Negative selection in response to high-affinity ligands might be due to increased TCR occupancy or a slower off rate (kinetic proof-reading). Although discrepancies exist between blocking experiments and genetically deficient mice, TCR signal and a second costimulatory signal might be required for negative selection. The kinetics of mitogen-activated protein kinase (MAPK) signaling might determine positive- vs. negative-selection signals. Extracellular signal-regulated kinase (ERK) is induced more rapidly during negative selection, which might determine the triggering of transcriptional factors, NUR77 and NF-B (Werlen *et al.*, 2003; Palmer, 2003).

Precursor T-cells are not self-renewing. Apoptosis occurs easily, and only some cells of this compartment differentiate into double-positive mature T-cells. A scale-up expansion of this population presents a challenge, with the foregoing available regulatory genes newly identified and modern manipulation tools in hand. Fetal thymus organ culture systems and suspension cultures with dissociated thymic epithelial cells and, more recently, a cell line transgenic with various notch-ligand, for studying the microenvironment, the mechanism, and the differentiation and education of T-cells, are available (ref. cited in Chen, 2000). However, how to expand precursor T-cells *ex vivo* without differentiation and apoptosis remains a challenge. It is possible to expand transiently paraaortic splanchnopleural-derived precursor T-cells in culture and perish quickly. The physical environment of culturing, such as varying the O<sub>2</sub> level of the incubator where the fetal organ culture was set up, was shown to help the survival of (precursor) T-cells. Free radicals promote molecules that lead to the apoptotic pathway. Thus, reducing the concentration of local O<sub>2</sub> with a high level of N<sub>2</sub> in the incubator or supplying the cultured cells with a high density of stroma cells favors the survival of (precursor) T-cells.

### Stage 5: Mature T-Cells and Memory T-Cells

Using cultures of mature T-cells in the presence of APCs (antigen-presenting cells) and recombinant cytokines, one can study the growth and differentiation of T-cells from a variety of sources. Long-term mouse and human T-cell clones are also available. For unknown reasons, T-cells can be maintained as clones in culture far longer than B-cells. However, long-term human T-cell clones, even from healthy donors, have not been reimplanted into patients. Human T-cells (mainly natural killer cells) grown in the presence of cytokines in a short-term culture have been reimplanted into autologous cancer patients. No study was reported to evaluate their long-term repopulating potentiality in the human severe combined immunodeficient (SCID) model or the self-renewal property of long-term mouse T-cell clones *in vivo*. Most CD8<sup>+</sup> and CD4<sup>+</sup> T-cells have a short life span. Memory T-cells have been well studied, but in reality they do not exist in abundance and can be demonstrated *in vivo* only by repeated priming with antigen. They are very diffi-

cult to define at the cellular and molecular levels. There is no isotype 3'-end downstream of the TCR constant region for class switching to occur. Somatic hypermutation of the TCR-beta gene has never been claimed, and it is controversial whether the TCR-alpha gene is hypermutable. Memory T-cells are thus defined using criteria such as accelerated cellular responses, distinct pathways of lymphocyte recirculation *in vivo*, distinct DNA motifs of TCR genes, cytokine-producing pattern and diminishing expression of surface markers (ref. cited in Chen, 2000), and functional and antigen requirements. In mice, memory CD4<sup>+</sup> T-cells are CD45RO, L-selectin (MEL-14)<sup>low</sup>. This is the equivalent of human CD45RO, keeping in mind that the CD45R family (A, B, C, and O) may not be the best marker to define naive versus memory T-cells. Because foreign antigens do not always quickly elicit unprimed T-cells, memory T-cells must exist, but the commitment, the mechanism of development, and the maintenance of these cells are unknown. Memory T-cells are thought to be generated either when T-cells acquire specificity to kill or to help during thymic education, or they are generated during the mature stage.

### Memory CD8<sup>+</sup> T-Cells

Because cell-bound antigen on APCs (see later, for details) and more than one signal are required for educating T-cells to perform effector functions instead of becoming tolerized, work on the generation of CD8<sup>+</sup> memory T-cells has been mainly *in vivo*, using viruses. Is it possible to prevent cytotoxic T-cells from performing their function by releasing granzymes. If so, what happens to committed CD8<sup>+</sup> T-cells? Do they die, or become anergic, or become memory cells? A study addressing the avoidance of granzyme B-induced apoptosis in target cells is interesting in this regard (ref. cited in Chen, 2000). Dephosphorylation of cdc2 was shown to be a critical step in granzyme B-induced apoptosis in the targets of cytotoxic T-cells. A nuclear kinase encoded by the *wee 1* gene was transiently expressed and shown to induce phosphorylation of the tyrosine residues of cdc2 kinase, and that in turn provoked mitosis and the rescue of target cells. Because cytotoxic T-cells are subject to being killed by their colleagues, the apoptosis pathway in these cytotoxic T-cells could be similar to that of the target cells. The priming, clonal expansion, and differentiation into memory T-cells can be achieved. The expansion of memory T-cells can be demonstrated in culture. Besides viral peptide antigen, recent examples are the use of mycobacterial glycolipids as the antigen, the antigen processed by CD1b, CD1e (Gilleron *et al.*, 2004; Sallet *et al.*, 2005). Primed T-cells are harvested from a human adult and stimulated *in vitro* with antigen with hIL-2. The T-cell clone can demonstrate the killing of cells infected with *Mycobacterium tuberculosis* (discussed further later).

It is interesting to learn that DNA methylation may contribute to regulation of mouse T effector cell function (Makar and Wilson, 2004a). In Dnmt1<sup>-/-</sup> (the maintenance DNA

methyltransferase), silencing of IL-4, IL-5, IL-13, and IL-10 in CD8 T-cells was abolished, and expression of these T<sub>H</sub>2 cytokines increased drastically as compared with that of control CD8 T-cells. T<sub>H</sub>2 cytokine expression also increased in Dnmt1<sup>-/-</sup> CD4 T-cells, but the increase was less than for CD8 T-cells. As a result, both Dnmt1<sup>-/-</sup> CD4 and CD8 T-cells expressed high and comparable amounts of T<sub>H</sub>2 cytokines. Loss of Dnmt1 had more subtle effects on IL-2 and IFN expression and did not affect the normal bias for greater IL-2 expression by CD4 T-cells and greater IFN expression by CD8 T-cells or the exclusive expression of perforin and granzyme B by the CD8 T-cells. Dnmt1 and DNA methylation seem to be necessary to prevent cell-autonomous T<sub>H</sub>2 cytokine expression in CD8 T-cells, but they are not essential for maintaining proper T-cell subset-specific expression of T<sub>H</sub>1 or CTL effectors. Thus, transcription factors and DNA methylation are complementary and nonredundant mechanisms by which the T<sub>H</sub>2 effector program is regulated.

### Memory CD4<sup>+</sup> T-Cells

Like memory CD8<sup>+</sup> T-cells, the generation of memory CD4<sup>+</sup> T-cells is studied *in vivo*. This population of cells has been well characterized in mice. Effector memory CD4<sup>+</sup> cells in mouse spleen against the soluble protein antigen keyhole limpet hemocyanin (KLH) and other protein antigen were found to be CD45RO, L-selectin<sup>-</sup>, CD44<sup>+</sup> and to produce elevated levels of IL-4 (ref. cited in Chen, 2000). Whether this population of cells can be expanded *ex vivo* remains unknown. Because T-cells of IL-2 knockout mice survive much longer than those of conventional mice, they may be useful for studying the development of memory T-cells. Moreover, molecules such as Fas and Fas ligands of the apoptotic pathways play critical roles in determining the fate of cells after activation. The Bcl-2/bcl-x family seems to function by helping the survival of cells via action on the intermediate steps of apoptosis. In the future, genes controlling the cell death pathway may play critical roles in the development of, and the subsequent genetic manipulation of, memory T-cells. It is important to improve the conditions for growing CD8<sup>+</sup> T-cells *in vitro*, because for tumor therapy, the generation of tumor-specific CD8<sup>+</sup> T-cells is a critical step.

Although surface markers and the life span of a population of T-cells equivalent to those of the mouse system have been documented, ethical and safety considerations have prevented a systematic study of human memory T-cells *in vivo*. The possibility of producing human CD4<sup>+</sup> T-cells on a large scale has been reported. By stimulating peripheral, resting T-cells with cytokines such as IL-2, anti-CD28, and solid-phase anti-CD3, they reported that survival and proliferation of CD4<sup>+</sup>, but not CD8<sup>+</sup>, T-cells could be greatly promoted. What remains to be shown are the specificity and function of these cells and how they are related to the regulation of the Bcl-2/bcl-x family and CD95 (Fas/apo-1) ligand and whether they are candidate memory CD4<sup>+</sup> T-cells or abortive T-cells.

### Role of APC, Toll-Like Receptor, in the Activation of CD4<sup>+</sup>, T<sub>h</sub>1 vs. T<sub>h</sub>2 Pathways

The recognition and stimulation of antigen epitopes by T-cells requires that antigen molecules first be processed to become fragmented epitope and presented properly by APCs (antigen-presenting cells). The APCs identified so far are macrophages, dendritic cells, and B-cells when in the process of T-B-cell cooperation. T-cells will only recognize the antigenic epitope when it is embedded in MHC (major histocompatibility complexes, H2 in mouse and HLA in humans), which enables the immune system to distinguish its own cells from foreign cells.

Foreign antigens are great engineers. The nature of the antigen to be processed by the APCs decides which processed antigenic epitopes are to be presented by which kind of T-cells and how to influence the reaction of the immune system. For example, when cytosol enters the host, viral proteins will be digested by proteasomes to become fragmented epitopes and be presented on the surface of APCs in complex with class I MHC. Their interaction with the CD8<sup>+</sup> T-cells will enable them to become cytotoxic T-cells to perform cell-mediated immunity.

The soluble bacterial (with exception, see next section) toxins, phagocytized into acidic vesicles in APCs, will be processed by the vesicular proteases, and the fragmented epitopes will be presented on the surface of APCs in complex with class II MHCs. In macrophages, foreign proteins within the acidic phagocytic vesicles will be digested and presented on their surface in complex with class II MHC, similar to APCs. These epitopes are recognized by the CD4<sup>+</sup> helper T-cells and will cause immune responses such as the activation of phagocytes and antibody production by activated B-cells.

In recent years, two major subsets, T<sub>h</sub>1–T<sub>h</sub>2, have been recognized in the population of CD4<sup>+</sup> T-cells. T<sub>h</sub>1 is shown to secrete gamma interferon and to help cell-mediated responses. T<sub>h</sub>1 stimulation results in local inflammatory responses, including the activation of macrophages, and the production of complement-fixing and -opsonizing antibodies. T<sub>h</sub>2 is shown to secrete IL-4 and IL-3, IL-5, and IL-13 and to help antibody-mediated responses. T<sub>h</sub>2 activation leads to the production of IgG and IgE and to the activation of basophil and eosinophils to fight against allergens and parasites.

It has been a puzzle as to how T<sub>h</sub>1 vs. T<sub>h</sub>2 cells recognize and distinguish the epitopes of foreign antigen on APCs, since both require the presence of class II MHCs. The discovery of the mammalian equivalent of TLRs (Toll-like receptors) derived from *Drosophila* “Toll” and the subsequent study of the signaling via such receptors are among the exciting reports to address such a question. TLRs are found on the surface of APCs (dendritic cells, macrophages); so far, 11 different receptors have been shown to bind to various cellular components of microorganisms.

As shown in Fig. 51.2 (O'Neill, 2004) and in Burdin *et al.* (2004), the binding of most of these components to the preferable TLRs produces a differential signaling cascade that stimulates immune response in favor of T<sub>h</sub>1 over T<sub>h</sub>2. Stimulation of TLR7 (and TLR8 in humans) (Heil *et al.*, 2004; Diebold *et al.*, 2004) by synthetic imidazoquinoline compounds leads to activation of the T<sub>h</sub>2 pathway; while stimulation of TLR4 by MPL (monophosphoryl Lipid A) and LPS and stimulation of TLR9 by unmethylated CpG of bacterial DNA lead to activation of the T<sub>h</sub>1 pathway. The activation, via TLR1, 2, 6, TLR3, TLR5, and the new addition of TLR11 (Zhang *et al.*, 2004) leading to which specific pathway remains open. Future understanding of the mechanism and the accompanying design of the tools will lead to the engineering of T<sub>h</sub>1 versus T<sub>h</sub>2 pathways (O'Neill, 2004; O'Neill *et al.*, 2003; Takeda *et al.*, 2003; Glazer and Nikaido, 2007).

### Role of CD1 in the T-Cell Recognition of Lipid Antigen

Besides peptide-protein antigen, which stimulates the Th1, Th2 pathway via TLR on APCs, lipid antigen activates T-cells by CD1 molecules, which is independent of TLR. Recent studies have shown that CD1 molecules are lipid antigen-presenting molecules that offer the lipid antigens to the TCR of T-cells, resembling MHC presentation of peptides, a MHC class III molecule. They have no structural homology with TLR, though they are also present on APCs. It may cause confusion, derived from the fact that some lipids are TLR ligands and therefore trigger the classical TLR-dependent responses on specific interaction. Some lipids are recognized by the immune system as classical antigens, resembling peptides associated with MHCs, whereas other lipids trigger the TLR innate receptors. Little is known about the delivery of lipid antigens from either extracellular compartments or CD1<sup>+</sup> cells to CD1<sup>+</sup> APCs. Apolipoprotein E is indicated to be involved in binding lipid antigens and delivering them to APC (Schumann and De Libero, 2006).

A panel of T-cell clones with different lipid specificities isolated from *Mycobacterium tuberculosis* was established. A novel lipid antigen belonging to the group of diacylated sulfoglycolipids, Ac2SGL (2-palmitoyl or 2-stearoyl-3-hydroxyphthioceranoyl-2'-sulfate-alpha-alpha'-D-trehalose), was identified. Ac2SGL is mainly presented by CD1b after internalization in a cellular compartment with low pH. Ac2SGL-specific T-cells release interferon-gamma, efficiently recognize *M. tuberculosis*-infected cells, and kill intracellular bacteria. The presence of Ac2SGL-responsive T-cells *in vivo* is strictly dependent on previous contact with *M. tuberculosis* but independent of the development of clinically overt disease. These properties identify Ac2SGL as a promising candidate to be tested in novel vaccines against tuberculosis (Gilleron *et al.*, 2004). Another isolated molecule, PIM6 (hexamannosylated phosphatidyl-myoinositols), stimulates CD1b-restricted T-cells after partial digestion of the oligomannose moiety by lysosomal alpha-mannosidase, and soluble CD1e, one of the CD1 family

**FIG. 51.2.** Going down the Toll mine. Toll-like receptors (TLRs) provide a repertoire for sensing pathogen-derived molecules during the innate immune response. TLRs in endosomal membranes detect bacterial and viral nucleic acids. The relative contribution of each TLR to the innate immune response is not yet known because pathogens contain multiple ligands specific for several different TLRs. The signaling pathways associated with each TLR are different, although they share common components. Specific signals may emanate from the adapter proteins recruited by each TLR (MyD88, Mal, Trif, and Tram). One important question concerns how the immune response is tailored to each pathogen according to the activation of specific signaling pathways triggered by different pathogen products (O'Neill *et al.*, 2003). HSV-1, herpes simplex virus 1; LPS, lipopolysaccharide; RSV, respiratory syncytial virus (corrected following the erratum, *Science*, postdate 4 June 2004); MMTV, mouse mammary tumor virus; Porin (bacterium, not influenza). From O'Neill (2004) with permission. The figure has been modified following the erratum in *Science*, postdate 4 June 2004, i.e., Porin is a bacterial component and not viral and is shifted from the grey region upward to the green region.

members, is required for the processing. Recombinant CD1e was able to bind glycolipids and assist in the digestion of PIM6. It is proposed that CD1e helps expand the repertoire of glycolipidic T-cell antigens to optimize antimicrobial immune responses through glycolipid editing (de la Salle *et al.*, 2005). How CD1 present lipid antigens to T-cells has been reviewed and graphically explained (De Libero and Mori, 2005).

### Innate Immunity and T Regulatory Cells

Recently, another heterogeneous population of T-cells has been re-identified, the so-called Treg (T regulatory) or suppressor cells. They can be innate or induced. The current literature is rather confusing. Here only a simplified overview is given.

The subset of Treg cells can be identified using different surface markers and the secreted cytokines. They include (1) naturally occurring T-cells possessing CD4<sup>+</sup> CD25<sup>+</sup> Nrp1<sup>+</sup>

Foxp3<sup>+</sup> TGF beta<sup>+</sup> and (2) cells induced in the periphery following antigen exposure, such as Treg1 cells possessing CD4<sup>+</sup> CD25<sup>+</sup> Foxp3<sup>+</sup> IL10<sup>+</sup> IFN gamma<sup>+</sup> TGF beta<sup>+</sup> IL5<sup>+</sup>, Th3 cells possessing CD4<sup>+</sup> CD25<sup>+</sup> Foxp3<sup>+</sup> TGF beta<sup>+</sup> IL-4<sup>+</sup> IL-10<sup>+</sup>, and Treg cells possessing CD8<sup>+</sup> CD25<sup>low</sup> foxp3<sup>+</sup> IL-10<sup>+</sup> TGF beta<sup>+</sup> (Bruder *et al.*, 2004). The cells express Foxp3 (fork-head/winged helix transcription factor), which appears to play a key role in supporting their action (Fontenot *et al.*, 2003).

APCs are essential in the activation of Treg cells; the immature APCs can support the differentiation of Treg cells. Targeting of antigens to immature dendritic cells has been shown to result in antigen-specific T-cell tolerance *in vivo*, which implies that some autoimmune diseases, transplant rejection, and allergy can be treated. The mechanism of suppression could be multiple and is not entirely known; the tools for such study are under development. One possibility is to tolerate the APCs, and the other is via the activation of

Treg. Treg cells can down-regulate Th1 and Th2 responses. Direct cell contact through binding of cell surface molecules such as CTLA4 (cytotoxic T-cell-associated Antigen 4) on Treg cells to CD80 and CD86 molecules on T cytotoxic cells results in the suppression. The local production of immunosuppressive cytokines such as TGF $\beta$  and IL10 also results in suppression. Suppression requires the appropriate colocalization of Treg and T effector cells in different tissue and may involve interference with the T-cell receptor signaling that triggers transcription factors important in regulating effector cell function, such as IL2 gene transcription (von Boehmer, 2005).

Treg are usually anergic (do not respond or proliferate to antigen stimulation) and IL2 dependent and proliferate poorly in culture. The truly naive CD4<sup>+</sup> T-cells can be converted into Treg cells expressing Foxp3 by targeting of peptide-agonist ligands to dendritic cells or by changing culture conditions, such as adding TGF- $\beta$  or reducing IL2. Treg cell populations induced in minute antigen conditions could subsequently be expanded by delivery of higher- or immunogenic-dose antigen (Kretschmer *et al.*, 2005). Since this field is young, how to conduct large-scale production is still developing. Transgenic expression of Foxp3 into antigenic primed CD4<sup>+</sup> T-cells to become Treg cells could be further developed by improving vectors (Jaekel *et al.*, 2005).

## Stage 6: Precursor B-Cells

Mouse and human precursor B-cells have been characterized extensively. Surface markers and molecular events of precursor lymphoid to precursor B-cells at intermediate stages of development have been defined (Table 51.1, Fig. 51.3, Hoffmann *et al.*, 2003). The markers for peripheral B-cells at different stages are summarized in Table 51.2 (Matthias and Rolink, 2005).

### Mouse Pre-B-Cell Lines

In the mouse system, with the help of several stroma cell lines and recombinant growth factors such as IL7 (Chen, 2000), it becomes feasible to expand mouse pre-B-cells without gross differentiation. On release from the stroma cells and IL7 and in the presence of the bacterial mitogen LPS, some pre-B-cell lines differentiate into plasma cells. Pre-B-cell clones have been established from various lymphoid organs of wild-type mice, transgenic mice, and knock-out mice. Thus, both somatic and genetic manipulation of these cell lines becomes possible. Some pre-B-cell lines have been used to repopulate SCID mice and RAG-2 knock-out mice. Injected cells migrate to bone marrow, lymph nodes, peritoneal cavity, and spleen. Plasma cells, mature B-cells, and pre-B-cells were detected in the host. The percentage of cells that mature into various B compartments seems to vary from experiment to experiment.

However, several questions remain to be answered. Do these pre-B-cell lines retain the capacity to expand? Are these cells self-renewing *in vivo*, as stem cells must be? The critical experiment of repeatedly transferring donor pre-B-cells from one host to another, to show that the implanted cells are still precursor B-cells, has not yet been done.

Pax5 signatures the commitment to B-cell lineage. It is interesting that pre-B-cells established from pax5<sup>-/-</sup> mice differentiated into T-cells, myeloid cells, dendritic cells, and osteoclasts but not mature B-cells in SCID mice. The data indicate that the microenvironment, which plays a role in keeping pre-B-cells committed to the B-cell lineage, may be missing in the pax5<sup>-/-</sup> mice. BAFF (B-cell activation factor, BLYS) belongs to the TNF family, and its receptors have a critical role in the transition from immature to mature B-cells (Matthias and Rolink, 2005).

Due to its potential to develop into mature B-lymphocytes and also into antibody-secreting plasma cells, which can be performed either *in vitro* or *in vivo*, mouse pre-B-cells have been subjected to genetic modification to become a vehicle to generate and secrete human antibodies against a variety of infectious antigens in SCID mice. The genetically modified pre-B-cells can be subjected to T-cell-dependent stimuli, inducing somatic hypermutation in the human antibody constructs. In this way, affinity-matured antibodies can be generated, allowing the development of therapeutic antibodies with the pharmacological efficacies.

### Curiosities of Growing Human Precursor B-Cells

The question of whether human precursor B-cells can expand *ex vivo* is open. Several reports claim it is possible by using either primary mixed human or mouse stroma cells (ref. cited in Chen, 2000). When subjected to mixed stroma cells and cytokines such as IL-7, most human bone marrow cells expand for a limited period and then either perish or differentiate. The culture conditions established seem to be only for short-term expansion of pre-B-cells. However, no normal human pre-B-cell lines have been established. This distinguishes mouse and human precursor B-cells. The study of human pre-B-cells cannot be separated completely from the study of human HSCs and HPCs, given the complexity of the cell types involved and the difficulty in establishing human stroma cell lines. The establishment of human stroma cell lines supporting the growth of human pre-B-cells is critical. The failure lies partially in the inability of adherent cells derived from human bone marrow (stroma cells) to proliferate well under normal culture conditions with conventional sera.

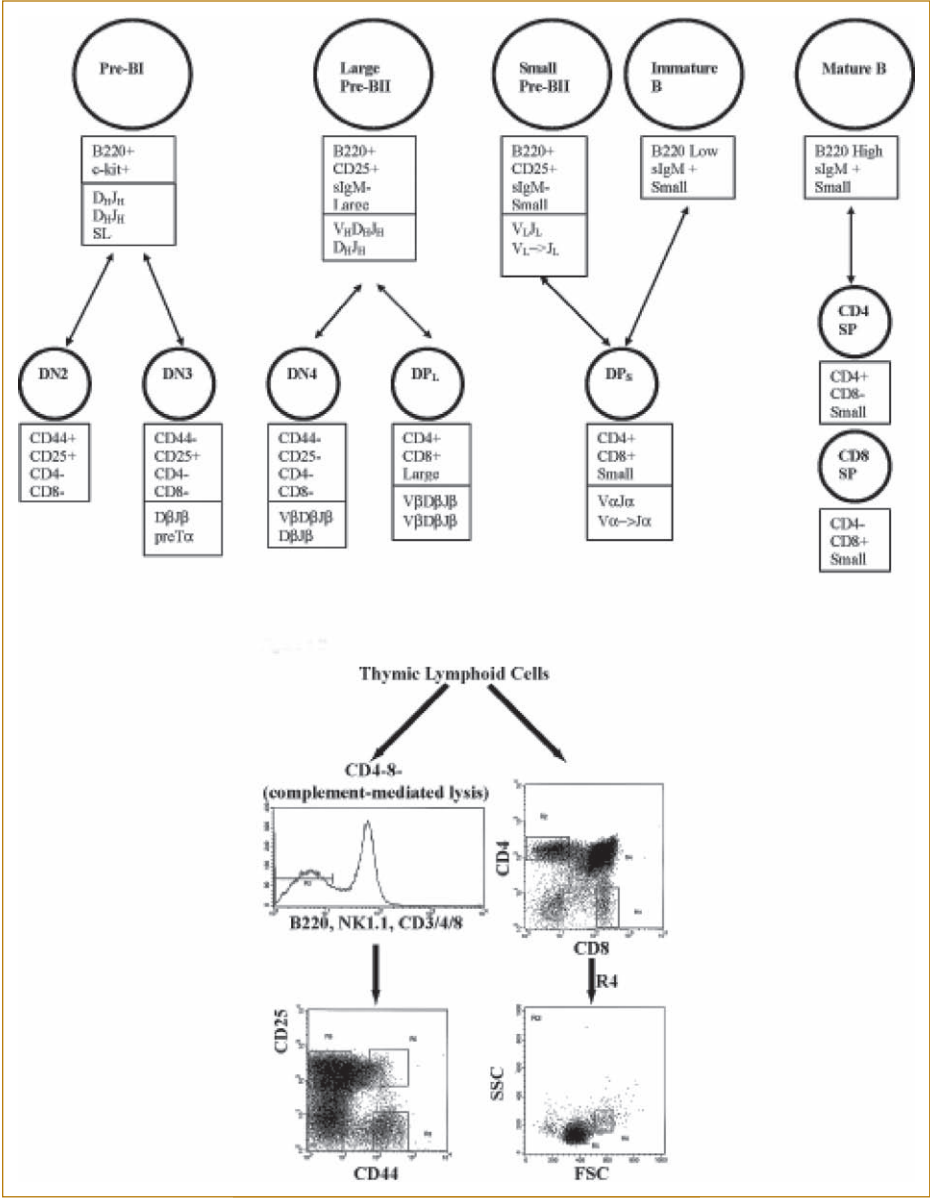

Methods for immortalizing human cells include transfecting plasmids or retroviruses containing oncogenes such as SV40 T antigen. One group (J. Dando, personal communication) has done that with human fetal bone marrow, and many stroma cell lines have been established; a few cell lines are partially characterized for supporting the growth and expansion of cord blood stem cells. Cell proliferation is

a prerequisite for the stable integration of transgenes into chromosomes and for immortalization. A breakthrough for human HSCs and pre-B-cells would be to establish stroma cell lines for B lymphopoiesis and to optimize the conditions for the growth of stroma cells, as has been done for human MSCs (ref. cited in Chen, 2000). In recent years, MSCs have been shown to expand to large quantity when selected lots of FCS are used. Prolonged culturing of MSCs under such conditions generates abnormalities of chromosome and tumors when transplanted in immunoincompetent mice (Rubio *et al.*, 2005).

### Stage 7: Memory B-Cells

B-cells with surface Ig isotypes such as IgG, IgA, and IgE, which possess higher affinities for antigen, are generally defined as memory B-cells. In human beings, CD38<sup>+</sup>, CD20<sup>+</sup> germinal center B-cells can be distinguished from memory CD38<sup>+</sup>, CD20<sup>+</sup> B-cells and CD38<sup>+</sup>, CD20<sup>+</sup> plasma cells. In mice, until recently there were no reliable surface markers to distinguish memory B-cells from plasma cells and mature primary B-cells.

The mechanisms of memory B-cell generation are unknown and have been the subject of debate for decades. Memory B-cells are mature B-cells that have encountered antigen that have been activated but not tolerized and have switched to higher-affinity isotypes. IgM-secreting plasma cells, Syndecan-1/CD138<sup>+</sup>, are terminal cells destined to die. It is unknown how memory B-cells develop *in vivo*. *In vitro*, at least two systems may generate memory B-cells: the germinal center-like culture system and the suspension culture system, wherein resting B-cells are activated by LPS plus anti- $\mu$ . These B-cells are activated, alive, proliferating, and nonabortive, but they are not plasma cells.

#### A System Stimulating Germinal Centers *In Vitro* to Culture B-Cells

In a culture environment that mimics the germinal center in lymphoid organs, B-cells survive better and live longer. A germinal center-like environment is a culture system that provides cytokines and supporting cells from either purified follicular dendritic cells (FDCs) from mouse spleen (ref. cited in Chen, 2000) or stroma cells (L-cells transfected with CD40 ligand called CD154, or fibroblasts). Both human and mouse B-cells survive for two weeks instead of three to four days, and absolute cell numbers increase two- to threefold.

The *in vitro* germinal center culture system developed was designed to study the differentiation of mouse B-cells into plasma cells rather than to maintain long-term B-cells *in vitro*. Mouse FDCs are nonproliferating, terminally differentiated cells of unknown origin. However, other studies reported that the primary mouse FDCs could be partially replaced by fibroblast cell lines expressing CD154. The cytokines, required to maintain mature B-cells in growth phase and differentiation, are controversial. For mouse B-cells,

combined IL-2, IL-4, and IL-5 induce differentiation into mature cells; for further differentiation into plasma cells, IL-6 seems to be essential.

For human B-cells, IL-2 plus IL-10, combined IL-3, IL-6, IL-7, and combined IL-2, IL-6, IL-10 have been reported to play roles in plasma cell differentiation. Cellular interactions, including those mediated by CD40 and CD154, are critical in the generation of both memory B-cells and plasma cells. If CD154 is removed in the secondary culture, human B-cells differentiate into plasma cells. These memorylike cells are neither cell lines nor cell clones; rather, they are a mixed B-cell type with a limited life span (up to a few weeks), and they preferentially switch to certain Ig isotypes, such as IgG and IgA. The data suggest that down-regulation of the J chain may not be essential during the development of memory B-cells.

IL-21, a newly identified cytokine affecting T-cells, NK-cells, and B-cells, signaling through IL-21 receptor and the common cytokine receptor gamma-chain ( $\gamma_c$ ), has recently been shown to play a role in stimulating the differentiation of mouse (Ozaki *et al.*, 2004) and human B-cells (Ettinger *et al.*, 2005). In mouse, IL-21 is shown to promote differentiation of B-cells into postswitch and plasma cells, using IL-21-transgenic mice and hydrodynamics-based gene delivery of IL-21 plasmid DNA *in vivo* and *in vitro*. IL-21 induces expression of Blimp-1 and Bcl-6, which play a role in the development of autoimmune disease. When human B-cells were stimulated through the BCR (B-cell receptor, anti-IgM), IL-21 induced minimal proliferation, IgD down-modulation, and small numbers of plasma cells. In contrast, after anti-CD40 activation, IL-21 induced extensive proliferation, class switch recombination, and plasma cell differentiation. On cross-linking both BCR and CD40, IL-21 induced the largest numbers of plasma cells. IL-21 drove both CD27<sup>+</sup> memory cells and naive cord blood B-cells to differentiate into plasma cells. In the latter, the effect of IL-21 was more potent than the combination of IL-2 and IL-10. IL-21 costimulation induced the expression of Blimp-1 and AICD (activation-induced cytidine deaminase), required for CSR (class switch recombination), secreted IgG from B-cells, but did not induce somatic hypermutation. IL-2 enhanced the effects of IL-21, whereas IL-4 inhibited IL-21-induced plasma cell differentiation.

#### A Suspension Culture System for Stimulating B-Cells with LPS Plus Anti- $\mu$

Systems for the short-term culture of primary splenic lymphocytes have long existed (Chen, 2000). These systems are invaluable for studying the proliferation and differentiation of B-cells, T- and B-cell interaction, the priming of B-cells by antigen, and the mechanism of memory B-cell generation. If B-cells could be kept alive and untolerized but could be prevented from becoming IgM secretory plasma cells, they might become memory B-cells. One example is the finding that when stimulated with a bacterial mitogen,

LPS, some B-cells die and some proliferate and become plasma cells (Chen, 2000). When stimulated with anti- $\mu$ , most B-cells die right away, some proliferate and exhibit growth arrest at G<sub>1</sub> phase and then die two days later, and none become plasma cells. When stimulated with LPS plus anti- $\mu$ , most B-cells proliferate and none become plasma cells. This non-plasma-cell phenomenon has been known as an antidifferentiation effect, and it was postulated to be a way to generate memory B-cells (Chen, 2000). Through the efforts of many, the molecular mechanism of this antidifferentiation phenomenon became clear. In the presence of the two stimuli, B-cells proliferate maximally, over 90% being in the cell cycle (Chen, 2000), but IgM secretion is turned off. The block has been shown to be primarily at the level of nuclear RNA processing of the  $\mu_m$ -to- $\mu_s$  switch. Inducible nuclear factors binding to the pre-mRNA secretory polyA site have been reported, though the nature of these factors remains unclear.

### Transcription Factors Active in the Development of Plasma Cells

On activation of B-cells, many transcription factors (Oct-2, OBF-1, Blimp-1, or PRDI-BF1 in human, Xbp1, IRF4, Bcl6, etc.) become engaged in the production and secretion of Ig genes. B-cell-preferential transcription factors include Oct-2 (Chen, 2000) and Blimp-1 (ref. cited in Chen, 2000, and more recent publication). The transcription factors play a role in the decision to switch from  $\mu_m$  to  $\mu_s$ . Blimp-1 is described as a cofactor of transcription factor pu.1 and was shown to bind to multiple Ig-enhancer motifs and the J-chain regulatory element. It is crucial for the transcription of  $\mu$ ,  $\kappa$ , and J chains. Blimp-1 is active in many cell lines and drives the maturation of B-cells into Ig-secreting cells. Blimp-1 has been shown to down-regulate *c-myc* in B-cell lines.

Oct2 is POU-domain-containing transcription factor, binds to the  $\mu$  intron enhancer octamer motif, on which they can form a ternary complex with the coactivator OBF1, and is essential in transcriptional activation of the  $\mu$  chain. Oct2 and OBF-1 are mainly B-cell-specific protein. Mice that lack Oct2 are not viable, and mature B-cells are affected (Corcoran *et al.*, 1993). It was shown that Oct2 and the J chain are highly expressed in LPS-stimulated B-cells and are diminished in LPS + anti- $\mu$ -stimulated B cells. It has been shown that Blimp-1 is highly expressed in LPS-stimulated B-cells and is diminished in LPS + anti- $\mu$ -stimulated B-cells. On the other hand, sterile gamma chain is highly expressed in the latter system. Transfection of *Blimp-1* into LPS + anti- $\mu$ -activated B cells provoked them to become IgM-secreting plasma cells. The data indicated that transcription factors such as Oct2 and Blimp-1 are tightly regulated in plasma cell development. If one postulates that LPS + anti- $\mu$ -stimulated B-cells represent some stage in memory B-cell development, then the down-regulation of Oct2 and Blimp-1 reflects the specific transcriptional regu-

lation when B-cells make the commitment to the memory cell pathway instead of the plasma cell pathway. The identification of such candidate transcription factors that control memory B-cell commitment provided a powerful genetic tool to manipulate the turning on and off of these lineages at will.

To determine the role of Blimp-1 in the functioning of plasma cells, mice in which the gene encoding Blimp-1 could be deleted in an inducible manner have been produced (Shapiro-Shelef *et al.*, 2005). Deletion of Blimp-1 either *in vitro* or *in vivo* leads to loss of previously formed B220<sup>low</sup> Syndecan-1/CD138<sup>high</sup> plasma cells. Assays have been performed and show that Blimp-1 is required for the formation and maintenance of long-lived plasma cells.

Interestingly, Blimp-1 is also active in some differentiated cells, including a human osteosarcoma cell line (Gyory *et al.*, 2004), terminal differentiated myeloid cell lines, and freshly isolated bone marrow mononuclear cells. Its action is shown to be antiproliferative by inhibiting *c-myc* gene expression pathway (Tamura *et al.*, 2003). In B-cells, Blimp-1 is required for terminal differentiation of B-cells to plasma cells. The optimal DNA recognition sequence for Blimp-1 has been identified. The consensus is very similar to a subset of sites recognized by IRFs (IFN regulatory factors) that contain the sequence GAAAG. Competition experiments showed that Blimp-1, IRF-1, and IRF-2 have similar binding affinities for functionally important regulatory sites containing this sequence. Blimp-1 does not bind to all IRF sites and does not recognize IRF-4/PU.1 or IRF-8 sites lacking the GAAAG sequence. Chromatin immunoprecipitation studies showed that Blimp-1, IRF-1, and IRF-2 all bind the IFN-beta promoter *in vivo*, as predicted by the *in vitro* binding parameters, and in cotransfections Blimp-1 inhibits IRF-1-dependent activation of the IFN-beta promoter. Thus, Blimp-1 competes *in vivo* with a subset of IRF proteins and helps predict the sites and IRF family members that may be affected (Kuo and Calame, 2004).

The human Blimp-1, PRDI-BF1, is a DNA-binding protein involved in postinduction repression of IFN-beta gene transcription in response to viral infection. In terminal differentiation of B-cells, it has an essential function in driving differentiation and therein silences multiple genes. In the osteosarcoma cell line U2OS, PRDI-BF1 is shown to assemble silent chromatin over the IFN-beta promoter through recruitment of the histone H3 lysine methyltransferase G9a. G9a is recruited only when in a complex with PRDI-BF1. G9a catalytic activity is required for the accumulation of methylated histone H3 and transcriptional silencing mediated by PRDI-BF1 *in vivo*. It establishes a mechanism for the recruitment of G9a, the main mammalian euchromatic methyltransferase, and defines non-embryonic targets of G9a (Gyory *et al.*, 2004). G9a can target the specific silencing of IFN-beta gene expression and blocking of V(D)J recombination (Osipovich *et al.*, 2004). A drawing of the model of action is shown in Makar and Wilson (2004b).

Microarray experiments of the expression of Blimp-1 indicate that it regulates a large set of genes of plasma cell expression signature (Sciammas and Davis, 2005). Blimp-1 affects numerous aspects of plasma cell maturation, ranging from migration, adhesion, and homeostasis to antibody secretion. It regulates immunoglobulin secretion by affecting the nuclear processing of the mRNA transcript and by affecting protein trafficking by regulating genes that impact the activity of the endoplasmic reticulum. The differentiation events that Blimp-1 regulates appear to be modulated, depending on the activation state of the B-cell, and hint at the complexity of Blimp-1 and the genetic program that it initiates to produce a pool of plasma cells.

There is a concerted activation-suppression of transcriptional factors during B-cell differentiation; besides the foregoing examples, see also the review by Matthias and Rolink (2005). In (human) germinal center B-cells, a set of genes has been shown to be involved in the differentiation: down-regulation of Bcl-6, which is implied to transform B-cells, activation of Blimp-1/PRDI-BF1, modulation of Myc, and the up-regulation of the Mad1 and Mad4 transcription factors. Recent data have suggested that Mad1 acts as a transcriptional repressor of Bcl-6 (Lee *et al.*, 2006). In addition, IRF4/Mum1 is expressed in germinal center cells and CD138<sup>+</sup> plasma cells (Buettnner *et al.*, 2005). Transcription factor E47 is required for CSR (class switch recombination), at least in part, via expression of AICD (activation-induced cytidine deaminase). Id2 has been identified as a negative regulator of E47 (Frasca *et al.*, 2004). Bach2 is a B-cell-specific transcription repressor interacting with the small Maf proteins, whose expression is high only before the plasma cell stage. It is critical for CSR and somatic hypermutation (SHM) of Ig genes. In Bach2<sup>-/-</sup> mice, B-cells produced IgM, as did wild-type cells, and abundantly expressed Blimp-1 and XBP-1, critical regulators of the plasmacytic differentiation, indicating that Bach2 was not required for the plasmacytic differentiation itself. However, they failed to undergo efficient CSR. These findings define Bach2 as a key regulator of antibody response and provide insight into the orchestration of CSR and SHM during plasma cell differentiation (Muto *et al.*, 2004). Mitf (microphthalmia-associated transcription factor) is highly expressed in naive B-cells, where it antagonizes the process of terminal differentiation through the repression of IRF-4. Defective Mitf activity results in spontaneous B-cell activation, antibody secretion, and autoantibody production. Conversely, ectopic Mitf expression suppresses the expression of IRF-4, CD138<sup>+</sup> plasma cells, and antibody secretion. Mitf regulates B-cell homeostasis by suppressing the antibody-secreting fate (L. Lin *et al.*, 2004).

The role of Xbp1 (X-box binding protein 1), another transcriptional factor (besides Blimp-1) essential for the differentiation of B-cells into plasma cells, has been studied (Shaffer *et al.*, 2004). By using microarray analyses, a set of genes have been defined whose induction during mouse plasmacytic differentiation is dependent on Blimp-1 and/or

Xbp1. Blimp-1<sup>-/-</sup> B-cells failed to up-regulate most plasma cell-specific genes, including Xbp1. Differentiating Xbp1<sup>-/-</sup> B-cells induced Blimp-1 normally but failed to up-regulate genes encoding many secretory pathway components. Conversely, ectopic expression of Xbp1 induced a wide spectrum of secretory pathway genes and physically expanded the endoplasmic reticulum. Xbp1 increased cell size, lysosome content, mitochondrial mass and function, ribosome numbers, and total protein synthesis. Xbp1 is essential to coordinate diverse changes in cellular structure and function resulting in the characteristic phenotype of professional secretory cells.

## IX. CONCLUDING REMARKS AND PROSPECTS FOR LYMPHOCYTE ENGINEERING

I have discussed and summarized the current understanding of the expansion of lymphoid cells and their precursors *ex vivo* at certain stages of lymphopoiesis. I have tried to address the feasibility of expanding lymphoid cells under controlled growth conditions; that is, we need to expand untransformed, nonmalignant cells. In general, in order to maintain the status of cell survival and growth without apoptosis and differentiation, cytokines and cell contact with feeder cells are required. Fundamental questions regarding the engineering of lymphoid cells and their precursors for therapeutic purposes remain and can be traced to our current understanding of the immune system. Do we ask too much for the survival in culture of cells that are programmed to die? From extensive studies in gene-manipulated mice, it is possible to generate antigen-specific memory T-cells; it is still puzzling that there is no good systematic study of human memory cells in culture, although the surface markers are defined.

If there is massive programmed cell death during the development from HSCs to lymphoid precursors and from pre-T-cell to T-cell maturation, I wonder whether it is realistic to try to produce enough HSCs, HPCs, and precursor lymphoid cells for therapeutic purposes. In several clinical protocols, expansion of cells *ex vivo* for the purpose of reinfusion into patients is limited to as few passages as possible in order to avoid mutation and contamination *in vitro*. Bioreactors for large-scale production of cells in liquid suspension using cytokines are available. However, they are not designed for coculturing of stem cells with stroma cells. With advances in culture technology and bioreactors and with increased supply of recombinant cytokines, it becomes possible to obtain a quantity sufficient for reimplantation from 10 ml of bone marrow cells. However, under these conditions, very few cells engage in lymphopoiesis. Thus, to grow the HSCs and HPCs consistently and to favor lymphopoiesis, there is a great need for a better way to grow human stem cells using human stroma cell lines. The current study using transcription factors such as HoxB4, Cdx4, and mMix

to manipulate the behavior of hESCs *in vitro* may be a promising approach.

In view of the massive apoptosis at several stages of lymphopoiesis, it is amazing that mouse precursor B-cells can grow normally, become lines and clones, and retain the potential to differentiate *in vitro* and *in vivo*. To grow cells from other stages of lymphopoiesis, it might be advantageous to use cells from the many available mutated mice.

The future of cell-based immune therapy lies in the *ex vivo* expansion of cells. Because the techniques to establish ligand-regulatable vectors are available, the derived cell lines will become available and will become valuable resources for many purposes. Other areas remain to be improved, including the search for novel markers of true

HSCs and precursor lymphocytes; better sources of HSCs and HPCs, such as cord blood and fetal tissues and hES cells; improved retroviral vectors; and large-scale culture systems for expansion of HSCs and HPCs and precursor lymphoid cells.

With advances in genetic tools and mutated-mice technology, it is possible to turn on or off the transcription factors that control the differentiation of cells. With the recent discovery and understanding of Toll-like molecules on APCs to stimulate  $T_H1$  vs.  $T_H2$ , and the rediscovery of Treg cells, the approaches to fight against autoimmune diseases, allergy, and transplantation rejection will become accessible. Thus, immunology will continue to be a very exciting field.

## X. ACKNOWLEDGMENTS

The author wishes to thank Lucien Caro, Don Gerson, Anja Holtz, Raju Pareek, and all our other colleagues for fruitful discussions and critical reading and editing of this chapter. The author also wishes to thank Hiroshi Nikaido for sharing his work before publication and to Harald von Boehmer, Gerhard Hoffmann, Fritz Melchers, Christoph Wilson, Nicolas Burdin, Alexander Aiuti, Gennardo De Libero, Lucia

Mori, Patrick Matthias, Ton Rolink, Kris Bowles, and Roger Pedersen for giving permission to use figures and tables and for conducting kind discussions and for providing inside information on their work. This work is supported by funds from third-party agencies: German DFG, the European Community, W-P, CMU.

### I. INTRODUCTION

Chronic and acute renal failure are significant clinical problems whose frequencies are expected to increase with the prevalence of diabetes, hypertension, and obesity. In the United States, more than 320,000 patients were undergoing dialysis treatment for end-stage renal disease in 2003, at a cost of more than \$14 billion. This cohort is expected to increase to 650,000 by 2010 (Nolan, 2005). Yet the mortality associated with long-term dialysis remains unacceptably high. In the case of acute renal failure due to ischemia or nephrotoxicity, the frequency of mortality in the clinical setting has not dipped significantly below 50% (Liu, 2003), despite many advances in understanding the cell physiology of renal injury. Clearly, new approaches for the treatment of chronic and acute renal disease must be explored. Tissue engineering, cell replacement therapies, and novel growth and differentiation factors are being developed to address the limitations of current therapies. All of these approaches rely on the knowledge base obtained from basic developmental studies in the kidney, regarding the potency of renal stem cells and the genetic basis of epithelial cell differentiation and proliferation. This chapter outlines the basic elements of renal development and renal stem cell biology and discusses current and future applications of emerging technologies for renal disease.

### II. KIDNEY DEVELOPMENT

A detailed description of early renal development and nephron formation is covered in several recent reviews (Dressler, 2002; Kuure *et al.*, 2000). In brief, the mammalian kidney develops from a region of mesoderm, called the *intermediate mesoderm*, that lies between the axial and lateral plate mesoderm along the mediolateral axis of the embryo. The earliest morphological indication of unique derivatives arising from the intermediate mesoderm is the formation of the pronephric duct, or primary nephric duct. This single-cell-thick epithelial tube runs bilaterally, beginning from the mid-thoracic region, to a posterior cavity called the *cloaca*. As it grows, it induces a linear array of epithelial tubules, which extend medioventrally and are thought to derive from mesenchyme surrounding this duct (Fig. 52.1). The tubules are referred to as *pronephric* or *mesonephric*, depending on their position and degree of development, and represent an evolutionarily more primitive excretory system that forms transiently in mammals until it is replaced by the adult, or metanephric, kidney. The adult kidney, or metanephros, is formed at the caudal end of the nephric duct when an outgrowth, called the *ureteric bud* or *metanephric diverticulum*, extends into the surrounding metanephric mesenchyme. Outgrowth, or budding, of the epithelia requires signals emanating from the mesenchyme.

**FIG. 52.1.** Urogenital derivatives of the intermediate mesoderm. A schematic of the mammalian urogenital tract during development is shown. The embryonic stages (E9.5) are shown as days postfertilization in the mouse. The primary nephric duct extends anterior to posterior, inducing mesonephric tubules along the ventral aspect. At the posterior end, the metanephric mesenchyme is induced by the ureteric bud, an outgrowth of the nephric duct. Ureteric bud-derived signals induce condensation of the mesenchyme, whereas mesenchymal signals induce branching morphogenesis in the bud epithelia. By E13, male- and female-specific urogenital derivatives become apparent.

Genetic and biochemical studies indicate that outgrowth of the ureteric bud is mediated by the transmembrane tyrosine kinase RET, which is expressed in the nephric duct, and the secreted neurotrophin GDNF, which is expressed in the metanephric mesenchyme.

Once the ureteric bud has invaded the metanephric mesenchyme, inductive signals emanating from the bud initiate the conversion of the metanephric mesenchyme to epithelium (Fig. 52.2). The induced, condensing mesenchymal cells aggregate around the tips of the bud and will form a primitive polarized epithelium, the renal vesicle. Through a series of cleft formations, the renal vesicle forms first a comma and then an S-shaped body, whose most distal end remains in contact with the ureteric bud epithelium and fuses to form a continuous epithelial tubule. This S-shaped tubule begins to express genes specific for glomerular podocyte cells at its most proximal end, markers for more distal tubules near the fusion with the ureteric bud epithelia, and proximal tubule markers in between. Endothelial cells begin to infiltrate the most proximal cleft of the S-shaped body as the vasculature of the glomerular tuft takes shape. At this stage, the glomerular epithelium consists of a visceral and a parietal component, with the visceral cells becoming podocytes and the parietal cells the epithelia surrounding the urinary space. The capillary tuft consists of capillary endothelial cells and a specialized type of smooth muscle cell, termed the *mesangial cell*, whose origin remains unclear.

While these renal vesicles are generating much of the epithelia of the nephron, the ureteric bud epithelia continue

to undergo branching morphogenesis in response to signals derived from the mesenchyme. Branching follows a stereotypical pattern and results in new mesenchymal aggregates induced at the tips of the branches, as new nephrons are sequentially induced. This repeated branching and induction results in the formation of nephrons along the radial axis of the kidney, with the oldest nephrons being more medullary and the younger nephrons located toward the periphery. However, not all cells of the mesenchyme become induced and convert to epithelia; some cells remain mesenchymal and migrate to the interstitium. These interstitial mesenchymal cells, or *stromal cells*, are essential for providing signals that maintain branching morphogenesis of the ureteric bud and survival of the mesenchyme.

Defining the population of cells that generate the kidney depends in part on which stage is considered. At the time of metanephric mesenchyme induction, there are at least two primary cell types, the mesenchyme and the ureteric bud epithelia. Though these cells are phenotypically distinguishable, they do express some common markers and share a common region of origin. As development progresses, it was thought that most of the epithelium of the nephron was derived from the metanephric mesenchyme, whereas the branching ureteric bud epithelium generates the collecting ducts and the most distal tubules. This view has been challenged by cell-lineage tracing methods *in vitro*, which indicate some plasticity at the tips of the ureteric bud epithelium such that the two populations may intermingle (Qiao *et al.*, 1995). Thus, at the time of induction, epithelial cells can convert to mesenchyme, just as the mesenchymal

**FIG. 52.2.** Sequential conversion of the metanephric mesenchyme to renal epithelia. The metanephric mesenchymal cells are induced to condense around the tips of the invading ureteric bud. These condensations undergo conversion to a primitive epithelial vesicle, the renal vesicle. The renal vesicle is in close proximity to the branching ureteric bud epithelia and fuses to form a continuous epithelial tubule. At the S-shaped body stage, the most proximal cleft becomes vascularized by infiltrating endothelial precursors. The nephron takes shape as the podocyte precursors and endothelial cells intermingle to make the glomerular tuft and the tubular components proliferate and elongate.

aggregates can convert to epithelia. Regardless of how the mesenchyme is induced, the cells are predetermined to make renal epithelia. Thus, their potential as renal stem cells has begun to be explored. To understand the origin of the metanephric mesenchyme, we begin with the patterning of the intermediate mesoderm.

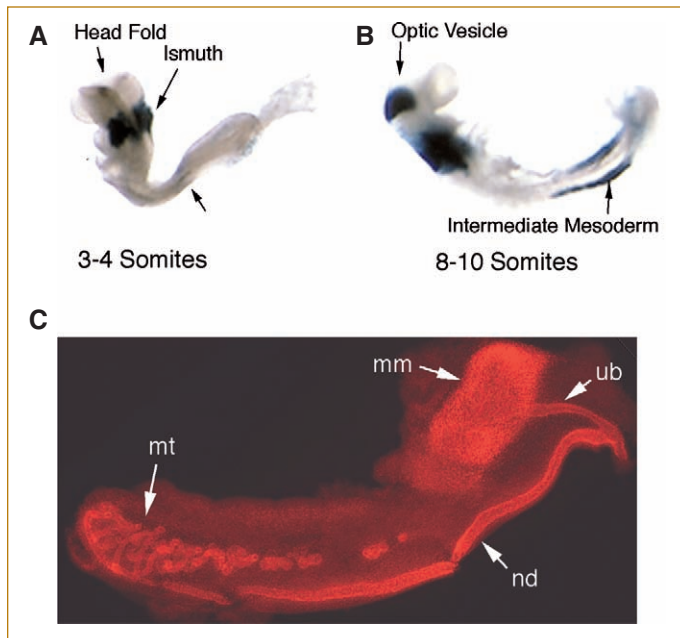

### III. GENES THAT SPECIFY EARLY KIDNEY CELL LINEAGES

The early events controlling the specification of the renal cell lineages may be common among the pro- and mesonephric regions. Indeed, many of the same genes expressed in the pronephric and mesonephric tubules are instrumental in early metanephric development. Some of these events that underlie regional specification have been studied in more amenable organisms, including fish and

amphibians, in which pronephric development is less transient and of functional significance.

#### Regionalization of the Mesoderm

While formation of the nephric duct is the earliest morphological evidence of renal development, the expression of intermediate mesodermal-specific markers precedes nephric duct formation temporally and marks the intermediate mesoderm along much of the A–P body axis. The earliest markers specific for the intermediate mesoderm are two transcription factors of the Pax family (Fig. 52.3), Pax2 and Pax8, which appear to function redundantly in nephric duct formation and extension (Bouchard *et al.*, 2002). The homeobox gene *lim1* is expressed in the intermediate mesoderm, but it is initially expressed in the lateral plate mesoderm before becoming more restricted (Tsang *et al.*, 2000).

**FIG. 52.3.** The activation of Pax2 expression in the intermediate mesoderm. **(A & B)** The embryos shown carry a Pax2 promoter driving the LacZ gene, and expression is visualized by staining for beta-galactosidase activity. One of the earliest markers for the nephrogenic region, Pax2 expression is activated around the 4–5-somite stage in the cells between the axial and lateral plate mesoderm (A). By the 8-somite stage (B), Pax2 marks the growing intermediate mesoderm, even before the nephric duct is formed. Pax2 is also expressed in parts of the nervous system, especially the mid-brain/hindbrain junction, known as the *rhombocephalic ismuth*, and in the optic placode and cup. **(C)** By E11, staining for Pax2 protein reveals expression in all epithelial derivatives of the intermediate mesoderm, including the nephric duct (nd), the mesonephric tubules (mt), the ureteric bud (ub) branching from the posterior duct, and the metanephric mesenchyme (mm).

Similarly, Odd-1 (Odd skipped related 1) is also expressed in a broad swath of lateral and intermediate mesoderm (James and Schultheiss, 2005). Genetics implicates all four genes in some aspects of regionalization along the intermediate mesoderm. In the mouse, Pax2 mutants begin nephric duct formation and extension but lack mesonephric tubules and the metanephros (Torres *et al.*, 1995). Pax2/Pax8 double mutants have no evidence of nephric duct formation and do not express the *lim1* gene (Bouchard *et al.*, 2002). Null mutants in *lim1* also lack the nephric duct and show reduced ability to differentiate into intermediate mesoderm-specific derivatives (Tsang *et al.*, 2000). Odd-1 mutants are able to generate a nephric duct that expresses Pax2 but do not have mesonephric tubules or evidence of a metanephros (Wang *et al.*, 2005). Since *lim1* expression precedes Pax2 and Pax8 and is spread over a wider area in the pre- and postgastrulation embryo and is Pax independent, it seems likely that maintenance and restriction of *lim1* expression within the intermediate mesoderm requires activation of the Pax2/8 genes at the 5–8-somite stage.

Are Pax2/8 sufficient, then, to specify the renal progenitors? This question was addressed in the chick embryo by Bouchard *et al.* (2002) using replication-competent retroviruses expressing a Pax2b cDNA. Ectopic nephric ducts were generated within the general area of the intermediate mesoderm on retrovirally driven Pax2b expression. These ectopic nephric ducts were not obtained with either *lim1* or Pax8 alone. Strikingly, the ectopic nephric ducts paralleled the endogenous ducts and were not found in more paraxial or lateral plate mesoderm. This would suggest that Pax2's ability to induce duct formation does require some regional competence, perhaps only in the *lim1*-expressing domain.

If Pax2/8 and *lim1* restriction in the intermediate mesoderm are the earliest events that distinguish the nephrogenic zone from surrounding paraxial and lateral plate mesoderm, the question then remains as to how these genes are activated. In the axial mesoderm, signals derived from the ventral notochord pattern the somites along the dorsal–ventral axis. Similar notochord-derived signals could also pattern mesoderm along the mediolateral axis. However, this does not appear to be the case. In the chick embryo, the notochord is dispensible for activation of the Pax2 gene in the intermediate mesoderm. Rather, signals derived from the somites, or paraxial mesoderm, are required for activation of Pax2 (Mauch *et al.*, 2000). More recently, James and Schultheiss (2005) used bone morphogenetic protein 2 (Bmp-2) to induce expression of intermediate mesodermal markers in a concentration-specific manner. *In vitro*, high levels of Bmp-2 induce a lateral plate mesodermal fate, whereas low concentrations generate more intermediate mesodermal tissue. Bmp expression is high in the dorsolateral overlying ectoderm. In an independent experiment, nephric duct formation can be inhibited if the overlying ectoderm is removed, yet duct formation is restored with exogenous Bmps (Obara-Ishihara *et al.*, 1999). The model proposed by James and Schultheiss suggests that factors within the axial mesoderm suppress the expression of intermediate mesodermal markers and that this suppression is lost at low concentrations of Bmps. In the *Xenopus* embryo, retinoic acid and activins are able to expand the pronephric region in animal cap assays, suggesting a positive role for these potential morphogens (Osafune *et al.*, 2002). Similarly, mouse embryonic stem cells respond to activin-A and retinoic acid by expressing many markers of the intermediate mesoderm and its derivatives (Kim and Dressler, 2005). Thus, the mediolateral patterning events appear to be driven by opposing signals to specify the intermediate mesoderm at the interface between lateral plate and axial mesoderm.

If Pax2/8 mark the entire nephric region (Fig. 52.3), there must be additional factors that specify the position of elements along the anterior–posterior (A–P) axis in the intermediate mesoderm. Such patterning genes could determine whether a mesonephric or metanephric kidney

is formed within the Pax2 positive domain. Among the known A–P patterning genes are members of the HOX gene family. Indeed, mice that have deleted all genes of the Hox11 paralogous group have no metanephric kidneys (Wellik *et al.*, 2002), though it is not clear whether this is truly a shift in A–P patterning or a lack of induction. A–P patterning of the intermediate mesoderm may also depend on the FoxC family of transcription factors. FoxC1 and FoxC2 have similar expression domains in the presomitic and intermediate mesoderm, as early as E8.5 (Kume *et al.*, 2000). As nephric duct extension progresses, FoxC1 is expressed in a dorso-ventral gradient with the highest levels near the neural tube and lower levels in the BMP4 positive ventrolateral regions. In FoxC1 homozygous null mutants, the anterior boundary of the metanephric mesenchyme, as marked by GDNF expression, extends rostrally (Kume *et al.*, 2000). This results in formation of a broader ureteric bud along the A–P axis and eventual duplication of ureters. Similar defects are observed in compound heterozygotes of FoxC1 and FoxC2, indicating some redundancy and gene dosage effects. Thus, FoxC1 and FoxC2 may set the anterior boundary of the metanephric mesenchyme, at the time of ureteric bud outgrowth, by suppressing genes at the transcriptional level.

### Genes That Function at the Time of Metanephric Induction

Induction and conversion of the metanephric mesenchyme to renal epithelia requires the concerted action of many genes. In Pax2 mutants, there is no evidence of ureteric bud outgrowth, despite the presence of a nephric duct. Ureteric bud outgrowth is controlled primarily by the receptor type tyrosine kinase RET, which is expressed on the nephric duct epithelia, the secreted signaling protein GDNF, which is expressed in the metanephric mesenchyme, and the GPI-linked protein GFR $\alpha$ 1, which is expressed in both tissues. Pax2 mutants have no ureteric buds because they do not express GDNF in the mesenchyme and fail to maintain high levels of RET expression in the nephric duct (Brophy *et al.*, 2001). Despite the lack of bud, the metanephric mesenchyme is morphologically distinguishable in Pax2 mutants. While lacking GDNF, it does express other markers of the mesenchyme, such as Six2 (Torres *et al.*, 1995). *In vitro* recombination experiments using Pax2 mutant mesenchyme, surgically isolated from E11 mouse embryos, and heterologous inducing tissues indicate that Pax2 mutants are unable to respond to inductive signals (Brophy *et al.*, 2001). Thus, Pax2 is necessary for specifying the region of intermediate mesoderm destined to undergo mesenchyme-to-epithelium conversion. In humans, the necessity of Pax2 function is further underscored because the loss of a single Pax2 allele is associated with renal-coloboma syndrome, which is characterized by hypoplastic kidneys with vesicoureteral reflux (Sanyanusin *et al.*, 1995).

A second essential gene for conversion of the metanephric mesenchyme to epithelia is Eya1, a vertebrate

homolog of the *Drosophila* eyes-absent gene. In mice homozygous for an Eya1 mutation, kidney development is arrested at E11 because ureteric bud growth is inhibited and the mesenchyme remains uninduced, though Pax2 and WT1 expression appears normal (Xu *et al.*, 1999). However, two other markers of the metanephric mesenchyme, Six2 and GDNF expression, are lost in the Eya1 mutants. The loss of GDNF expression most probably underlies the failure of ureteric bud growth. However, it is not clear if the mesenchyme is competent to respond to inductive signals if a wild-type inducer were to be used *in vitro*. The eyes-absent gene family is part of a conserved network that underlies cell specification in several other developing tissues. Eya proteins share a conserved domain but lack DNA binding activity. The Eya proteins interact directly with the Six family of DNA-binding proteins. Mammalian Six genes are homologs of the *Drosophila sina oculis* homeobox gene. This cooperative interaction between Six and Eya proteins is necessary for nuclear translocation and transcriptional activation of Six target genes (Ohto *et al.*, 1999). In humans, mutations in either Six1 (Ruf *et al.*, 2004) or Eya1 (Abdelhak *et al.*, 1997) are associated with branchio-oto-renal syndrome, further underscoring these genetic and biochemical interactions.

The Wilms' tumor suppressor gene, WT1, is another early marker of the metanephric mesenchyme and is essential for its survival. Wilms' tumor is an embryonic kidney neoplasia that consists of undifferentiated mesenchymal cells, poorly organized epithelium, and surrounding stromal cells. Expression of WT1 is regulated spatially and temporally in a variety of tissues and is further complicated by the presence of at least four isoforms, generated by alternative splicing. In the developing kidney, WT1 can be found in the uninduced metanephric mesenchyme and in differentiating epithelium after induction (Armstrong *et al.*, 1992; Pritchard-Jones *et al.*, 1990). Early expression of WT1 may be mediated by Pax2 (Dehbi *et al.*, 1996). Initial expression levels are low in the metanephric mesenchyme, but they become up-regulated at the S-shaped body stage in the precursor cells of the glomerular epithelium, the podocytes. High WT1 levels persist in the adult podocytes. In the mouse, WT1-null mutants have complete renal agenesis (Kreidberg *et al.*, 1993), because the metanephric mesenchyme undergoes apoptosis and the ureteric bud fails to grow out of the nephric duct. The arrest of ureteric bud growth is most probably due to lack of signaling by the WT1 mutant mesenchyme.

The transcription factor Gata-3 is also required for proper expression of RET in the nephric duct (Grote *et al.*, 2006). Gata-3 mutations exhibit increased duct cell proliferation and misdirected ureteric buds (Grote *et al.*, 2006; Lim *et al.*, 2000). Early expression of Gata-3 in the intermediate mesoderm requires Pax2/8, though direct regulation has not been demonstrated. In humans, Gata-3 is associated with hypothyroidism, deafness, renal anomalies, and

the so-called HDR syndrome, which is a result of haplo-insufficiency (Van Esch *et al.*, 2000).

#### IV. ESTABLISHMENT OF ADDITIONAL CELL LINEAGES

At the time of ureteric bud invasion, at least two cell lineages appear to be established, the metanephric mesenchyme and the ureteric bud epithelia (Fig. 52.4). As branching morphogenesis and induction of the mesenchyme progress, additional cell lineages are evident. The early E11.5 mouse metanephros contains precursors for most all cell types, including endothelial, stromal, epithelial, and mesangial cells. Yet it is far from clear if these cell types share a common precursor or if the metanephric mesenchyme is a mixed population of precursors. The latter point may well be true for the endothelial lineage. While transplantation studies with lineage markers indicate that the vasculature can be derived from E11.5 metanephric kidneys, the Flk1 positive endothelial precursors have been observed closely

associated with the ureteric bud epithelium, shortly after invasion, and are probably not derived from the metanephric mesenchyme. The lineages most likely to share a common origin within the metanephric mesenchyme are the stromal and epithelial. The maintenance of these two lineages is essential for renal development, for the ratio of stroma to epithelia is a critical factor for the renewal of mesenchyme and the continued induction of new nephrons.

#### Epithelia versus Stroma

What are the early events in the induced mesenchyme that separate the stromal lineage from the epithelial lineage? The inducing signal is most likely to be Wnt9b, because it is expressed in the ureteric bud and Wnt9b mouse mutants fail to induce the mesenchyme while still undergoing early branching morphogenesis (Carroll *et al.*, 2005). Wnt genes encode a family of secreted peptides that are known to function in the development of many tissues. In response to these Wnt-inductive signals, Pax2-positive cells aggregate at the tips of the ureteric bud. Subsequently, activation of Wnt4 in these early aggregates appears critical to promote polarization. Mice homozygous for a wnt-4 mutation exhibit renal agenesis, due to growth arrest shortly after branching of the ureteric bud (Stark *et al.*, 1994). Although some mesenchymal aggregation has occurred, there is no evidence of cell differentiation into a polarized epithelial vesicle. Expression of Pax2 is maintained but reduced. Thus, wnt-4 may be a secondary inductive signal in the mesenchyme that propagates or that maintains the primary induction response in the epithelial lineage.

The transcription factor BF-2 is expressed in uninduced mesenchyme and becomes restricted to those cells not undergoing epithelial conversion after induction (Hatini *et al.*, 1996). BF-2 expression is found along the periphery of the kidney and in the interstitial mesenchyme, or stroma. After induction, there is little overlap between BF-2 and the Pax2 expression domain, prominent in the condensing pretubular aggregates. Clear lineage analysis is still lacking, though the expression patterns are consistent with the interpretation that mesenchyme cells may already be partitioned into a BF-2-positive stromal precursor and a Pax2-positive epithelial precursor prior to or shortly after induction. Mouse mutants in BF-2 exhibit severe developmental defects in the kidney that point to an essential role for BF-2 in maintaining growth and structure (Hatini *et al.*, 1996). Early ureteric bud growth and branching is unaffected, as is the formation of the first mesenchymal aggregates. However, at later stages (E13–14) these mesenchymal aggregates fail to differentiate into comma- and S-shaped bodies at a rate similar to wild type. Branching of the ureteric bud is greatly reduced at this stage, resulting in formation of fewer new mesenchymal aggregates. The fate of the initial aggregates is not fixed, for some are able to form epithelium and most all express the appropriate early markers, such as Pax2, wnt-4, and WT1. Nevertheless, it appears that

**FIG. 52.4.** Major cell lineages of the kidney. Whether the kidney arises from a single renal stem cell or from multiple independent lineages remains to be determined. However, the basic differentiation scheme is becoming clearer. The cell-lineage relationships are outlined schematically, with dotted lines reflecting ambiguity in terms of direct lineages. The metanephric mesenchyme contains angioblasts and stromal and epithelial precursors. Whether angioblasts arise from mesenchymal cells or are a separate lineage that surround the mesenchyme is not entirely clear. Similarly, the origin of the mesangial cell is not well defined. Stromal and epithelial cells may share a common precursor, the metanephric mesenchyme, but segregate at the time of induction. The epithelial cell precursors, found in the aggregates at the ureteric bud tips, generate most all of the epithelial cell types in the nephron.

the BF-2-expressing stromal lineage is necessary to maintain growth of both ureteric bud epithelium and mesenchymal aggregates. Perhaps factors secreted from the stroma provide survival or proliferation cues for the epithelial precursors, in the absence of which the non-self-renewing population of mesenchyme is exhausted.

Some survival factors that act on the mesenchyme have already been identified. The secreted TGF- $\beta$  family member BMP7 and the fibroblast growth factor FGF2 in combination dramatically promote survival of uninduced metanephric mesenchyme *in vitro* (Dudley *et al.*, 1999). FGF2 is necessary to maintain the ability of the mesenchyme to respond to inductive signals *in vitro*. BMP7 alone inhibits apoptosis but is not sufficient to enable mesenchyme to undergo tubulogenesis at some later time. After induction, exogenously added FGF2 and BMP7 reduce the proportion of mesenchyme that undergoes tubulogenesis while increasing the population of BF-2 positive stromal cells (Dudley *et al.*, 1999). At least after induction occurs, there is a delicate balance between a self-renewing population of stromal and epithelial progenitor cells, the proportion of which must be well regulated by both autocrine and paracrine factors. Whether this lineage decision has already been made in the uninduced mesenchyme remains to be determined.

The role of stroma in regulating renal development is further underscored by studies with retinoic acid receptors. It is well documented that vitamin A deficiency results in severe renal defects (Lelievre-Pegorier *et al.*, 1998). In organ culture, retinoic acid stimulates expression of RET to increase dramatically the number of ureteric bud branch points, increasing the number of nephrons (Vilar *et al.*, 1996). Yet it is the stromal cell population that expresses the retinoic acid receptors, specifically *RAR $\alpha$*  and *RAR $\beta$ 2*. Genetic studies with *RAR $\alpha$*  and *RAR $\beta$ 2* homozygous mutant mice indicate no significant renal defects when either gene is deleted. However, double homozygotes mutant for both *RAR $\alpha$*  and *RAR $\beta$ 2* exhibit severe growth retardation in the kidney (Mendelsohn *et al.*, 1999). These defects are due primarily to decreased expression of the RET protein in the ureteric bud epithelia and limited branching morphogenesis. Surprisingly, overexpression of RET with a HoxB7/RET transgene can completely rescue the double RAR mutants (Batourina *et al.*, 2001). These studies suggest that stromal cells provide paracrine signals for maintaining RET expression in the ureteric bud epithelia and that retinoids are required for stromal proliferation. Reduced expression of stromal cell marker BF-2, particularly in the interstitium of RAR double mutants, supports this hypothesis.

### Cells of the Glomerular Tuft

The unique structure of the glomerulus is intricately linked to its ability to retain large macromolecules within the circulating bloodstream while allowing for rapid diffusion of ions and small molecules into the urinary space. The glomerulus consists of four major cell types: the endothelial

cells of the microvasculature, the mesangial cells, the podocyte cells of the visceral epithelium, and the parietal epithelium. The development of the glomerular architecture and the origin of the individual cell types are just beginning to be understood.

The podocyte is a highly specialized epithelial cell whose function is integral to maintaining the filtration barrier in the glomerulus. The glomerular basement membrane separates the endothelial cells of the capillary tufts from the urinary space. The outside of the glomerular basement membrane, which faces the urinary space, is covered with podocyte cells and their interdigitated foot processes. At the basement membrane, these interdigitations meet to form a highly specialized cell-cell junction, called the *slit diaphragm*. The slit diaphragm has a specific pore size to enable small molecules to cross the filtration barrier into the urinary space while retaining larger proteins in the bloodstream. The podocytes are derived from condensing metanephric mesenchyme and can be visualized with specific markers at the S-shaped body stage. While there are a number of genes expressed in the podocytes, there are only a few factors known to regulate podocyte differentiation. These include the WT1 gene, which is required early for metanephric mesenchyme survival but whose levels increase in podocyte precursors at the S-shaped body stage. In the mouse, complete WT1 null animals lack kidneys, but reduced gene dosage and expression of WT1 results in specific podocyte defects (Guo *et al.*, 2002). Thus, the high levels of WT1 expression in podocytes appear to be required and make these precursor cells more sensitive to gene dosage. The basic helix-loop-helix protein Pod1 is expressed in epithelial precursor cells and in more mature interstitial mesenchyme. At later developmental stages, Pod1 is restricted to the podocytes. In mice homozygous for a *Pod1*-null allele, podocyte development appears arrested (Quaggin *et al.*, 1999). Normal podocytes flatten and wrap their foot processes around the glomerular basement membrane. *Pod1*-mutant podocytes remain more columnar and fail to develop foot processes fully. Since Pod1 is expressed in epithelial precursors and in the interstitium, it is unclear whether these podocyte effects are due to a general developmental arrest because of the stromal environment or a cell autonomous defect within the *Pod1*-mutant podocyte precursor cells.

Within the glomerular tuft, the origin of the endothelium and the mesangium is less clear. At the S-shaped body stage, the glomerular cleft forms at the most proximal part of the S-shaped body, furthest from the ureteric bud epithelium. Vascularization of the developing kidney is first evident within this developing tuft. The origin of these invading endothelial cells has been studied in some detail. Under normal growth conditions, kidneys excised at the time of induction and cultured *in vitro* do not exhibit signs of vascularization, leading to the presumption that endothelial cells migrate to the kidney some time after induction.

However, hypoxxygenation or treatment with vascular endothelial growth factor (VEGF) promotes survival or differentiation of endothelial precursors in these same cultures, suggesting that endothelial precursors are already present and require growth differentiation stimuli (Tufro *et al.*, 1999; Tufro-McReddie *et al.*, 1997). It is likely that VEGF secretion by podocyte precursor cells helps attract neighboring endothelial cells into the proximal cleft (Eremina *et al.*, 2003). *In vivo* transplantation experiments using lacZ-expressing donors or hosts also demonstrate that the E11.5 kidney rudiment has the potential to generate endothelial cells, although recruitment of endothelium is also observed from exogenous tissue, depending on the environment (Hyink *et al.*, 1996; Robert *et al.*, 1996, 1998).

The data are consistent with the idea that cells within the E11.5 kidney have the ability to differentiate along the endothelial lineage. Are these endothelial cells generated from the metanephric mesenchyme? Using a lacZ knockin allele for the endothelial specific receptor Flk-1, Robert *et al.* (1998) showed that presumptive angioblasts are dispersed along the periphery of the E12 kidney mesenchyme, with some positive cells invading the mesenchyme along the aspect of the growing ureteric bud. At later stages, Flk-1-positive angioblasts were localized to the nephrogenic zone, the developing glomerular cleft of the S-shaped bodies, and the more mature capillary loops, whereas VEGF localizes to the parietal and visceral glomerular epithelium. Injection of neutralizing VEGF antibodies into newborn mice, at a time when nephrogenesis is still ongoing, disturbs vascular growth and glomerular architecture (Kitamoto *et al.*, 1997). The data suggest that endothelial cells originate independent of the metanephric mesenchyme and invade the growing kidney from the periphery and along the ureteric bud.

The mesangial cells are located between the capillary loops of the glomerular tuft and have been referred to as specialized *pericytes*. The pericytes are found within the capillary basement membranes and have contractile abilities, much like a smooth muscle cell. Whether the mesangial cell is derived from the endothelial or epithelial lineage remains unclear. However, genetic and chimeric analyses in the mouse have revealed a clear role for the platelet-derived growth factor receptor (PDGFR) and its ligand (PDGF). In mice deficient for either PDGF or PDGFR (Leveen *et al.*, 1994; Soriano, 1994), a complete absence of mesangial cells results in glomerular defects, including the lack of microvasculature in the tuft. PDGF is expressed in the developing endothelial cells of the glomerular tuft, whereas the receptor is found in the presumptive mesangial cell precursors. Using ES cell chimeras of *Pdgfr*<sup>-/-</sup> and *Pdgfr*<sup>+/+</sup> genotypes, only the wild-type cells could contribute to the mesangial lineage (Lindahl *et al.*, 1998). This cell-autonomous effect indicates that signaling from the developing vasculature promotes proliferation and/or migration of the mesangial precursor cells. Also, expression of PDGFR and smooth muscle actin

supports a model where mesangial cells are derived from smooth muscle of the afferent and efferent arterioles during glomerular maturation (Lindahl *et al.*, 1998).

## V. REGENERATION AND RENAL STEM CELLS

The ability of renal epithelial cells to regenerate after injury has prompted much speculation regarding the source of adult renal stem cells and the potential for utilizing such stem cells to enhance recovery further from both acute and chronic renal failure. Acute tubular necrosis (ATN) is the most common cause of acute renal failure in a clinical setting. Often the result of hypotension, surgical cross-clamping of the aorta or renal arteries, or exposure to toxicants, ATN has been studied in humans and in a variety of well-characterized animal models. Despite many advances in understanding the cell physiology of ischemic and toxic renal injury, the high frequency of mortality in the clinical setting has not dipped significantly below 50% (Liu, 2003). In animal models, ATN is the result of sublethal damage that is characterized by ATP depletion, mitochondrial dysfunction, loss of epithelial cell polarity, and loss of adhesion to extracellular matrix (Nony and Schnellmann, 2003). Such changes can trigger the intrinsic apoptotic response, most likely through cytochrome C release from mitochondria. Cells within the S3 segment of the proximal tubules and the thick ascending limb seem to be particularly sensitive to damaging agents (Shanley *et al.*, 1986; Venkatachalam *et al.*, 1978; Witzgall *et al.*, 1994). Despite significant cell death after ischemia/reperfusion, folic acid, or mercury chloride treatment, renal function in animal models of ATN can recover and proximal tubule morphology is restored if the extent of damage is sublethal.

The process of proximal tubule regeneration in rodent models of ATN has been characterized in much detail. After clearing of cellular debris, cells begin to repopulate the damaged area within a few days. The proliferation of cells within the S2 and S3 segments is accompanied by the expression of many immediate-early genes, such as c-myc and AP1 (Safirstein, 1994), and the reexpression of developmental regulatory genes such as Pax2 (Imgrund *et al.*, 1999). This reentry into the cell cycle and recapitulation of a developmental program has lent credence to the idea that surviving cells may dedifferentiate, migrate toward, and repopulate the denuded basement membrane of the S3 segment (Safirstein, 1999). While it is clear that sublethal injury promotes cell proliferation and the expression of dedifferentiation markers along the damaged proximal tubules, the origin of these newly differentiating cells has been the subject of some debate. The conventional models presumed that a subpopulation of viable, remaining cells could repopulate the damaged tubules (Nony and Schnellmann, 2003; Wallin *et al.*, 1992). Alternatively, the existence of a small population of renal stem cells within the environment of the adult

kidney was postulated as a potential source of renewable epithelia after injury (Al-Awqati and Oliver, 2002). More recently, a population of slowly dividing cells from the adult renal papilla was identified that could differentiate into multiple epithelial and parenchymal cell types in response to hypoxia (Oliver *et al.*, 2004). These findings support the idea that renal stem cells are intrinsic to the adult kidney.

In contrast, other investigators have pursued the potential of bone marrow–derived cells as a source of renal stem cells. Two early reports demonstrated bone marrow–derived proximal tubule cells in mice subject to ischemia and reperfusion (Kale *et al.*, 2003; Lin *et al.*, 2003). In these experiments, the majority of regenerated proximal tubule cells appeared to be derived from donor bone marrow stem cells either transplanted prior to or injected intravenously directly after injury. However, these findings lead to a great deal of skepticism and have since been disputed. The potential of whole bone marrow to contribute to proximal tubule regeneration many months after transplantation was examined in detail by Szczypka *et al.* (2005), who found little evidence for bone marrow–derived renal epithelial cells after induction of ATN by folic acid, despite numerous bone marrow–derived leukocytes within the renal interstitium. Similarly, Duffield *et al.* (2005) found no evidence for bone marrow–derived renal epithelial cells after injury, after careful examination of histological sections by deconvolution microscopy. In a follow-up article, Lin *et al.* (2005) were not able to demonstrate a significant fraction of bone marrow–derived renal epithelial cells after injury, despite their promising initial findings (Lin *et al.*, 2003).

In addition to whole–bone marrow transplants, purified human mesenchymal stem cells have been used for testing renal replacement in animal models. Such cells have been recombined with developing rodent kidneys *in vitro* and *in vivo* and show the potential to differentiate into tubular epithelium (Yokoo *et al.*, 2005, 2006). Injection of mesenchymal stem cells in rodent models of ischemia reduces the severity of renal failure, although this does not appear to be due to transdifferentiation into epithelia (Duffield *et al.*, 2005; Lange *et al.*, 2005). Finally, bone marrow–derived cells were used to rescue a genetic defect in a collagen IV chain (Col4A3), a mouse model of Alport's syndrome, such that the glomerular basement membrane was partially restored (Sugimoto *et al.*, 2006). Again, this correction does not necessarily mean that bone marrow–derived cells contributed to epithelial structures; rather, replacement of capillary endothelial cells by genetically corrected bone marrow cells could help remodel the aberrant glomerular basement membrane. Regardless of the cellular mechanisms involved, the data do point to significant therapeutic potential for mesenchymal stem cells and other bone marrow derivatives in alleviating certain renal insults.

An alternative source of renal stem cells may be the true embryonic stem (ES) cells isolated from the inner cell mass

of the blastocyst. On injection into developing kidney rudiments, ES cells can contribute to tubular epithelium and interstitium, suggesting that the local environment is conducive to differentiation of ES cells into renal derivatives (Steenhard *et al.*, 2005) (Fig. 52.5). Furthermore, the contribution of ES cells to renal epithelia can be enhanced if the cells are first differentiated *in vitro* by mesodermal factors known to be important for early renal development (Kim and Dressler, 2005). A combination of retinoic acid, activin, and BMP7 was shown to stimulate expression of early renal markers in embryoid bodies cultured *in vitro* (Fig. 52.5). Once these renal progenitor cells were injected into a developing kidney they were able to contribute exclusively to the renal proximal and distal tubules. Strikingly, ES cell derivatives were never found in the glomerulus, suggesting that an essential factor for podocyte differentiation was missing.

The above outlined experiments with ES cells highlight some of the difficulties regarding development and cell-lineage specification in the kidney. A prospective renal stem cell should be self-renewing and able to generate all of the cell types in the kidney, including epithelial, glomerular, mesangial, and stromal. Whether this can be achieved by a single cell or requires multiple progenitor cell types is still not clear. In simplest terms, all of the cells in the kidney could be generated by a single stem cell population, as outlined in Fig. 52.4. Yet even at the earliest stage of kidney development there are already two identifiable cell types, ureteric bud epithelia and metanephric mesenchyme. The presence of early endothelial precursors at the time of induction would make a third distinct cell type. If the three earliest cell types can actually be derived from the metanephric mesenchyme, a single stem cell may indeed exist and continue to proliferate as development progresses. At present, the data suggest that stroma and epithelia may share a common origin, whereas endothelial cells and their potential smooth muscle derivatives constitute a second lineage. However, even if there are three separate lineages already demarcated within the metanephric mesenchyme, the most relevant with respect to the repair of renal tissue is the epithelial lineage. Thus, if we consider the possibility of an epithelial stem cell, the following points would be among the criteria for selection: (1) The cells would most likely be a derivative of the intermediate mesoderm. (2) The cells would express a combination of markers specific for the metanephric mesenchyme. (3) The cells should be able to contribute to all epithelial components of the nephron, *in vitro* and *in vivo*.

The metanephric mesenchyme contains the renal progenitor cells but is essentially quiescent and does not proliferate in the absence of induction. However, growth conditions that mimic induction might be able to allow for the mesenchyme cells to proliferate while suppressing their differentiation into epithelium. If metanephric mesenchymal cells were able to proliferate *in vitro*, the markers they might express should include Pax2, lim1, WT1, GDNF, Six2,

**FIG. 52.5.** Embryonic stem cells can differentiate into renal epithelia. ES cells were allowed to form embryoid bodies and cultured with retinoic acid, activin, and BMP7 (RA7, panels A, C, E) as described by Kim and Dressler (2005). Control ES cells were allowed to form embryoid bodies but were cultured in media without additional differentiation promoting factors (B, D, F). **(A & B)** Embryoid bodies cocultured with inducing tissue, i.e., dorsal spinal cord, show large three-dimensional epithelial structures when treated with RA7 but not with media alone. **(C & D)** Epithelial structures generated from RA7-treated ES cells *in vitro* stain positive for Pax2 (red), E-cadherin (green), and laminin (blue), whereas controls show few Pax2-positive epithelia. **(E & F)** RA7-treated lacZ-positive cells (blue) injected into a developing kidney rudiment integrate into tubules (arrows), as indicated by staining for laminin (orange) and LTA lectin (proximal tubules, green). Many control ES cells remain as aggregates of mesenchyme (black arrows), although occasional ES cells are seen within tubules (white arrow).

and BF-2. Expression of these markers would indicate a mesenchymal cell that had not decided between the stromal and epithelial lineages. If cells express Pax2, WT1, and Wnt-4 but not BF-2, they could be an epithelial stem cell. Such epithelial stem cells, when injected into or recombined with an *in vitro* cultured metanephric kidney, should be able to make all of the epithelial cells along the proximal–distal axis of the nephron. Such epithelial stem cells could prove significant in regenerating damaged tubules in acute and chronic renal injury.

At present, the complexity of the kidney still impedes progress in the area of tissue- and cell-based therapies. Not

only must the right cells be made; they must be able to organize into a specialized three-dimensional tubular structure capable of fulfilling all of the physiological demands put on the nephrons. Developmental biology can provide a framework for understanding how these cells arise and what factors promote their differentiation and growth. While we may not be able to make a kidney from scratch, it seems within the realm of possibility to provide the injured adult kidney with cells or factors to facilitate its own regeneration. Given the high incidence and severity of acute and chronic renal insufficiency, such therapies would be most welcome indeed.

## VI. ACKNOWLEDGMENTS

I thank the members of my lab for valuable discussion regarding this topic, particularly Pat Brophy, Yi Cai, and Sanj

Patel. G.R.D. is supported by NIH grants DK054740, DK062914, and DK069689.

### I. INTRODUCTION

The rapid understanding of the cellular and molecular bases of organ function and disease processes will be translated in the next decade into new therapeutic approaches to a wide range of clinical disorders, including acute and chronic renal failure. Central to these new therapies are the developing technologies of cell therapy and tissue engineering, which are based on the ability to expand stem or progenitor cells in tissue culture to perform differentiated tasks and to introduce these cells into the patient either via extracorporeal circuits or as implantable constructs. Cell therapy devices are currently being developed to replace the filtrative, metabolic, and endocrinologic functions of the kidney lost in both acute and chronic renal failure. This chapter summarizes the current state of development of a renal tubule-assist device and a bioartificial hemofilter. These devices have the promise to be combined to produce a wearable or implantable bioartificial kidney for full renal replacement therapy that may significantly diminish morbidity and mortality in patients with acute or chronic renal disease.

The kidney was the first solid organ whose function was approximated by a machine and a synthetic device. In fact, renal substitution therapy with hemodialysis or chronic ambulatory peritoneal dialysis (CAPD) has been the only successful long-term *ex vivo* organ substitution therapy to date (Iglehart, 1993). The kidney was also the first organ to be successfully transplanted from a donor individual to an autologous recipient patient. However, the lack of widespread availability of suitable transplantable organs has

kept kidney transplantation from becoming a practical solution in most cases of chronic renal failure.

Although long-term chronic renal replacement therapy with either hemodialysis or CAPD has dramatically changed the prognosis of renal failure, it is not complete replacement therapy, because it provides only filtration function (usually on an intermittent basis) and does not replace the homeostatic, regulatory, metabolic, and endocrine functions of the kidney. Because of the nonphysiologic manner in which dialysis performs or does not perform the most critical renal functions, patients with end-stage renal disease (ESRD) on dialysis continue to have major medical, social, and economic problems (U.S. Renal Data System, 2004). Accordingly, dialysis should be considered as renal substitution rather than renal replacement therapy.

Tissue engineering of an implantable artificial kidney composed of both biologic and synthetic components could result in substantial benefits for patients by increasing life expectancy, mobility, and quality of life, with less risk of infection and with reduced costs. This approach could also be considered a cure rather than a treatment for patients. A successful tissue-engineering approach to the kidney depends on a thorough knowledge of the physiologic basis of kidney function.

### II. BASICS OF KIDNEY FUNCTION

The excretory function of the kidney is initiated by filtration of blood at the glomerulus, which is an enlargement of the proximal end of the tubule, incorporating a vascular

tuft. The structure of the glomerulus is designed to provide efficient ultrafiltration of blood, to remove toxic wastes from the circulation yet retain important circulating components, such as albumin. The regulatory function of the kidney, especially with regard to fluid and electrolyte homeostasis, is provided by the tubular segments attached to the glomerulus. The functional unit of the kidney is therefore composed of the filtering unit (the glomerulus) and the regulatory unit (the tubule). Together they form the basic component of the kidney, the nephron. In addition to these excretory and regulatory functions, the kidney is an important metabolic and endocrine organ. Erythropoietin, active forms of vitamin D, renin, angiotensin, prostaglandins, leukotrienes, kallikrein-kinins, various cytokines, and complement components are some of the endocrinologic compounds produced by the kidney. Because of the efficiency inherent in the kidney as an excretory organ, life can be sustained with only 5–10% of normal renal excretory function. Accordingly, the approach to a tissue-engineered construct becomes easier to entertain, especially because only a fraction of normal renal excretory function is required to maintain life (Humes, 2000).

The process of urine formation begins within the capillary bed of the glomerulus (Brenner and Humes, 1977). The glomerular capillary wall has evolved into a structure with the property to separate as much as one-third of the plasma entering the glomerulus into a solution of a nearly ideal ultrafiltrate. This high rate of ultrafiltration across the glomerular capillary is a result of hydraulic pressure generated by the heart and vascular tone of the preglomerular and postglomerular vessels as well as by the high hydraulic permeability of the glomerular capillary wall. The hydraulic pressure and permeability of the glomerular capillary bed are at least two times and two orders of magnitude higher, respectively, than those of most other capillary networks within the body (Landis and Pappenheimer, 1965). Despite this high rate of water and solute flux across the glomerular capillary wall, this same structure retards the filtration of important circulating macromolecules, especially albumin, so all but the lower-molecular-weight plasma proteins are restricted in the passage across this filtration barrier (Anderson and Quinn, 1974; Chang *et al.*, 1975; Brenner *et al.*, 1978).

This ultrafiltration process of glomeruli in normal human kidneys forms approximately 100 mL of filtrate every minute. Because daily urinary volume is roughly two liters, more than 98% of the glomerular ultrafiltrate must be absorbed by the renal tubule. The bulk of reabsorption, 50–65%, occurs along the proximal tubule. Similar to glomerular filtration, fluid movement across the renal proximal tubule cell is governed by physical forces. Unlike the fluid transfer across the glomerular capillary wall, however, tubular fluid flux is driven principally by osmotic and oncotic pressures rather than hydraulic pressure. Renal proximal tubule fluid absorption is based on active  $\text{Na}^+$  transport,

requiring the energy-dependent  $\text{Na}^+, \text{K}^+$ -ATPase located along the basolateral membrane of the renal tubule cell to promote a small degree of luminal hypotonicity (Andreoli and Schafer, 1978). This small degree of osmotic difference (2–3 mOsm/kg  $\text{H}_2\text{O}$ ) across the renal tubule is sufficient to drive isotonic fluid reabsorption, due to the very high diffusive water permeability of the renal tubule cell membrane. Once across the renal proximal tubule cell, the transported fluid is taken up by the peritubular capillary bed, due to the favorable oncotic pressure gradient. This high oncotic pressure within the peritubular capillary is the result of the high rate of protein-free filtrate formed in the proximate glomerular capillary bed (Knox *et al.*, 1983). As can be appreciated, an elegant system has evolved in the nephron to filter and reabsorb large amounts of fluid in bulk to attain high rates of metabolic product excretion while maintaining regulatory salt and water balance.

### III. TISSUE-ENGINEERING APPROACH TO RENAL FUNCTION REPLACEMENT

In designing an implantable bioartificial kidney for renal function replacement, essential features of kidney tissue must be utilized to direct the design of the tissue-engineering project. The critical elements of renal function must be replaced, including the excretory, regulatory transport, and endocrinologic functions. The functioning excretory unit of the kidney, as detailed previously, is composed of the filtering unit, the glomerulus, and the regulatory or transport unit, the tubule. Therefore, a bioartificial kidney requires two main units, the glomerulus and the tubule, to replace excretory function.

#### Bioartificial Hemofilter

The potential for a bioartificial glomerulus has been achieved with the use of polysulfone fibers *ex vivo* with maintenance of ultrafiltration in humans for a few days with a single device (Golper, 1986; Kramer *et al.*, 1977). The availability of hollow fibers with high hydraulic permeability has been an important advancement in biomaterials for replacement of glomerular ultrafiltration. Conventional hemodialysis for ESRD has used membranes in which solute removal is driven by a concentration gradient of the solute across the membranes and is, therefore, predominantly a diffusive process. Another type of solute transfer also occurs across the dialysis membrane via a process of ultrafiltration of water and solutes across the membrane. This convective transport is independent of the concentration gradient and depends predominantly on the hydraulic pressure gradient across the membrane. Both diffusive and convective processes occur during traditional hemodialysis, but diffusion is the main route of solute movement.

The development of synthetic membranes with high hydraulic permeability and solute-retention properties in convenient hollow-fiber form has promoted ESRD therapy

**FIG. 53.1.** Schematic of a tissue-engineered hemofilter composed of a microporous synthetic biocompatible hollow fiber, a preadhered extracellular matrix, and a confluent monolayer of autologous endothelial cells lining the luminal surface of the fiber. Arrows refer to vectorial ultrafiltrate formation.

based on convective hemofiltration rather than diffusive hemodialysis (Colton *et al.*, 1975; Henderson *et al.*, 1975). Removal of uremic toxins, predominantly by the convective process, has several distinct advantages, because it imitates the glomerular process of toxin removal with increased clearance of higher-molecular-weight solutes and removal of all solutes (up to a molecular-weight cutoff) at the same rate. Distinct differences are apparent between diffusive and convective transport across a semipermeable membrane. The clearance of a molecule by diffusion is negatively correlated with the size of the molecule. In contrast, clearance of a substance by convection is dependent on size, up to a certain molecular weight. The bulk movement of water carries passable solutes along with it in approximately the same concentration as in the fluid.

Development of an implantable device that mimics glomerular filtration will thus depend on convective transport (Fig. 53.1). This physiologic function has been achieved clinically with the use of polymeric hollow fibers *ex vivo*. Major limitations to the currently available technology for long-term replacement of filtration function include bleeding associated with required anticoagulation, diminution of filtration rate due either to protein deposition in the membrane over time or to thrombotic occlusion, and large amounts of fluid replacement required to replace the ultrafiltrate formed from the filtering unit. The use of autologous endothelial cell-seeded conduits along filtration surfaces may provide improved long-term hemocompatibility and hemofiltration *in vivo* (Kadletz *et al.*, 1992; Schnider *et al.*, 1988; Shepard *et al.*, 1986). A report detailing the capability of isolating angioblasts from peripheral blood makes this approach more readily achievable (Asahara *et al.*, 1997). Microfabricated capillary networks with microelectromechanical techniques and endothelial attachment and growth have made substantive advances recently (Shin *et al.*, 2004).

For differentiated endothelial cell morphology and function, an important role for various components of the extracellular matrix (ECM) has been demonstrated (Carey,

1991; Carley *et al.*, 1988). The ECM has clearly been shown to dictate phenotype and gene expression of endothelial cells, thereby modulating morphogenesis and growth. Various components of the ECM, including collagen type I, collagen type IV, laminin, and fibronectin, have been shown to affect endothelial cell adherence, growth, and differentiation. Of importance, ECM produced by Madin-Darby canine kidney (MDCK) cells, a permanent renal epithelial cell line, promotes endothelial cells to develop fenestrations. Fenestrations are large openings that act as channels or pores for convective transport through the endothelial monolayer and are important in the high hydraulic permeability and sieving characteristics of glomerular capillaries (Carley *et al.*, 1988; Milici *et al.*, 1985). Thus, the ECM component on which the endothelial cells attach and grow may be critical in the functional characteristics of the lining monolayer.

A second approach for a tissue-engineered device that may prove to have clinical utility is an implantable hemofilter with a capacity to produce 2–4 mL/min of ultrafiltrate. Although this rate of filtration is considerably less than the 10–15 mL/min rate required to correct the uremic state in ESRD patients, it is sufficient enough to improve solute clearance to lessen dialysis time and optimize clearance rates of urea and other uremic toxins. In addition, this rate of ultrafiltration from a stand-alone implanted hemofilter is small enough so that, with a urinary bladder capacity of 500–750 mL, a patient can tolerate the frequency of urination required from the filtrate's draining directly into the urinary tract system. Both of these intermediate devices will provide substantial experience to improve the durability, efficacy, and efficiency of an implantable hemofilter and a tubule-assist device to achieve the required hemofiltration rate of 15–20 mL/min and selective reabsorption for adequate clearance while avoiding volume depletion and intolerable urinary frequency.

An approach toward developing a durable and implantable bioartificial filtration device is to promote site-directed neovascularization *in vivo* (Thompson *et al.*, 1988). In this formulation, angiogenic factors (Folkman and Shing, 1992) can be delivered via endogenous or exogenous routes to induce targeted angiogenesis and neovascular beds among implanted biocompatible hollow fibers. These hollow follows are envisioned to act as collecting conduits for ultrafiltrate produced by the newly formed capillary network induced by the angiogenic factors. This formulation is based on the intrinsic property inherent in all capillary beds to produce ultrafiltrate (Landis and Pappenheimer, 1965). This filtrate, or *transudate*, will collect in the HF network rather than the usual physiologic sites consisting of the interstitial space and lymphatics. The vectorial filtrate flow will be from capillary through interstitium into hollow fiber and, ultimately, into an external drainage and collection system.

Our laboratory has just completed a series of studies in a rat model to promote via surgical techniques a tissue-engineered neovascular bed within an implant to permit

capillary ultrafiltration with and without angiogenic factors as a critical step to produce a bioartificial hemofilter. The results demonstrated a proof of concept of producing a bioartificial hemofiltration device with a durability of at least three to four months, the longest time period tested (Tiranathanagul *et al.*, 2005). Scale-up in large-animal models is being planned as a next step in this tissue-engineering program.

### Bioartificial Tubule

As detailed earlier, the efficiency of reabsorption, even though dependent on natural physical forces governing fluid movement across biologic as well as synthetic membranes, requires specialized epithelial cells to perform vectorial solute transport. Fortunately, a population of cells residing in the adult mammalian kidney has retained the capacity to proliferate and differentiate morphogenically into tubule structures *in vitro* (Humes and Cieslinski, 1992; Humes *et al.*, 1996) and can be used as the key cellular element of a tissue-engineered renal tubule device.

The bioartificial renal tubule can readily be conceived as a combination of living cells supported by polymeric substrata, using epithelial progenitor cells cultured on water- and solute-permeable membranes seeded with various biometric materials so that expression of differentiated vectorial transport and metabolic and endocrine functions is attained (Fig. 53.2). With appropriate membranes and biomatrices, immunoprotection of cultured progenitor cells has been achieved concurrent with long-term functional performance as long as conditions support tubule cell viability. This bioartificial tubule has been shown to transport salt and water effectively along osmotic and oncotic gradients (MacKay *et al.*, 1998).

A bioartificial proximal tubule satisfies a major requirement of reabsorbing a large volume of filtrate to maintain salt and water balance within the body. The need for additional tubule segments to replace other nephronal functions, such as the loop of Henle, to perform more refined homeostatic elements of the kidney, including urine concentration or dilution, may not be necessary. Patients with moderate renal insufficiency lose the ability to regulate salt

and water homeostasis finely, because they are unable to concentrate or dilute, yet are able to maintain reasonable fluid and electrolyte homeostasis due to redundant physiologic compensation via other mechanisms. Thus, a bioartificial proximal tubule, which reabsorbs isoosmotically the majority of the filtrate, may be sufficient to replace required tubular function to sustain fluid electrolyte balance in a patient with ESRD.

### Implantable Tissue-Engineered Kidney

The development of a bioartificial filtration device and a bioartificial tubule processing unit would lead to the possibility of an implantable bioartificial kidney consisting of a filtration device followed in series by the tubule unit, into which filtrate flows directly. This tubule unit should maintain viability, because metabolic substrates and low-molecular-weight growth factors are delivered to the tubule cells from the ultrafiltration unit (Nikolovski *et al.*, 1999). Furthermore, immunoprotection of the cells grown within the hollow fiber is achievable due to the impenetrability of immunologically competent cells through the hollow fiber (O'Neil *et al.*, 1997). Rejection of transplanted cells will, therefore, not occur. This arrangement thereby allows the filtrate to enter the hollow-fiber network internal compartments, which are lined with confluent monolayers of renal tubule cells for regulated transport function.

This device could be either used extracorporeally or implanted within a patient. The specific implant site for a bioartificial kidney will depend on the final configuration of both bioartificial filtration and tubule devices. As presently conceived, the endothelial-lined bioartificial filtration hollow fibers can be placed into an arteriovenous circuit using the common iliac artery and vein, similar to the surgical connection for a renal transplant. The filtrate is connected in series to a bioartificial proximal tubule, with the reabsorbate transported back into the systematic circulation. The processed filtrate exiting the tubule unit is then connected via tubing to the proximate ureter for drainage and urine excretion via the recipient's own urinary collecting system.

Although the ultimate goal of this approach is to construct a fully implantable bioartificial kidney with a hemofilter and tubular system, the pathway to achieve this goal will most likely occur via a staged developmental strategy, with each intermediate device providing both clinical therapeutic benefit and substantial experience in the use of more elementary tissue-engineered devices (Humes *et al.*, 1997). In this regard, the initial component of the bioartificial kidney to be developed for clinical evaluation will be an extracorporeal renal tubule-assist device (RAD) to optimize current hemofiltration approaches to treat the clinical disorder of acute renal failure (ARF).

### Development of a Renal Tubule-Assist Device

Replacement of the multivariate tubular functions of the kidney cannot be achieved with inanimate membrane

**FIG. 53.2.** Schematic of a tissue-engineered renal tubule. Renal epithelial cells form a confluent monolayer along the inner surface of a polysulfone hollow fiber with preadhered matrix molecules.

devices, as has been accomplished with the renal ultrafiltration process, but requires the use of the naturally evolved biologic membranes of the renal tubular epithelium. In this regard, the tissue engineering of a bioartificial renal tubule as a cell therapy device to replace these missing functions can be conceived as a combination of living cells supported on synthetic scaffolds (MacKay *et al.*, 1998; Nikolovski *et al.*, 1999). A bioartificial tubule can be constructed utilizing renal tubule progenitor cells (Humes and Cieslinski, 1992; Humes *et al.*, 1996), cultured on semipermeable hollow-fiber membranes on which extracellular matrix has been layered to enhance the attachment and growth of the epithelial cells (Timpl *et al.*, 1979). These hollow-fiber synthetic membranes not only provide the architectural scaffold for these cells but also provide immunoprotection, as has been observed in the long-term implantation of the bioartificial pancreas in a xenogeneic host (O'Neil *et al.*, 1997). The successful tissue engineering of a bioartificial tubule as a confluent monolayer has been achieved in a single hollow-fiber bioreactor system (Fig. 53.3) (MacKay *et al.*, 1998). The scale-up from a single-fiber system to a multifiber bioreactor and porcine renal proximal tubule cells has also been successfully demonstrated (Humes *et al.*, 1999b). Porcine cells were used initially because the pig is currently considered the best source of organs for both human xenotransplantation and immunoisolation cell therapy due to its anatomic and physiologic similarities to human tissue and the relative ease of breeding pigs in large numbers (Cozzi and White, 1995). The risk of viral transmission across species, however, requires human cells for clinical use.

The scale-up from a single hollow-fiber device to a multifiber bioartificial RAD device has proceeded with porcine renal proximal tubule cells grown as confluent monolayers along the inner surface of polysulfone immunoisolating hollow fibers (Humes *et al.*, 1999b). These hollow-fiber cartridges are packaged in bioreactor cartridges with membrane surface areas as large as  $0.7 \text{ m}^2$ , resulting in a device containing up to  $2.5 \times 10^9$  cells. *In vitro* studies of these RADs have demonstrated their retention of differentiated active vectorial transport of sodium, bicarbonate, glucose, and organic anions (Humes *et al.*, 1999b). These transport properties were suppressed with specific transport inhibitors. Ammoniogenesis and glutathione metabolism, which are important differentiated metabolic processes of the kidney, were also demonstrated in these devices. Synthesis of 1,25-dihydroxyvitamin  $\text{D}_3$  as a key endocrinologic metabolite was also documented. These metabolic processes were also shown to be regulated by important physiologic parameters and achieved rates comparable to those of a whole kidney.

The critical next step for clinical application of a renal tubule cell therapy device was to ascertain whether the RAD maintained differentiated renal functional performance, similar to that observed *in vitro*, and viability in an extracorporeal hemoperfusion circuit in an acutely uremic dog. The RAD was accordingly placed in series to a standard hollow-

**FIG. 53.3.** Electron micrograph of a tissue-engineered bioartificial renal tubule. The nucleus (N) is indicated; black arrows delineate apical microvilli (a differentiated morphologic characteristic of proximal tubule cells), and the white arrow identifies the tight junctional complex of a transporting epithelium.

fiber hemofiltration cartridge; the two cartridges had ultrafiltrate and postfiltered blood connections to duplicate the structural anatomy of the nephron and to mimic the functional relationship between the renal glomerulus and tubule (see Fig. 53.4). The successful completion of this step has been reported (Humes *et al.*, 1999a). Data show that fluid and electrolyte balances in the animals, as reflected by plasma parameters, were adequately controlled with the bioartificial kidney. In fact, plasma potassium and blood urea nitrogen levels were more easily controlled during RAD treatment as compared with sham control conditions. The step-up of oncotic pressure in the postfiltrate blood, which was delivered to the antiluminal space of the bioartificial proximal tubules, allowed the fractional reabsorption of sodium and water to achieve 40–50% of the ultrafiltrate volume, an amount similar to that seen in the nephron *in vivo*. Active transport of potassium, bicarbonate, and glucose by the RAD was demonstrated. Successful metabolic activity was also observed.

**FIG. 53.4.** The extracorporeal hemoperfusion circuit of a tissue-engineered kidney for the treatment of a patient with acute renal failure. The synthetic hemofilter is connected in series to the bioartificial renal tubule-assist device (RAD). Heat exchangers, flow and pressure monitors, and multiple pumps are required for optimal functioning of this extracorporeal device.

### Bioartificial Kidney in Acute Renal Failure

Current therapy for ischemic or toxic ARF or acute tubular necrosis (ATN) is predominantly supportive in nature. Uremia is treated with either intermittent hemodialysis or continuous hemofiltration, treatments that have had substantial impact on this disease process over the last 25 years. Patients with ATN, however, still have an exceedingly high mortality rate of greater than 50%, especially in sepsis (Schrier and Wang, 2004), despite maintenance of normal electrolyte balance and improvement in the uremic state. The high mortality is caused by the propensity of these patients to develop systemic inflammatory response syndrome followed by multiorgan dysfunction syndrome (Breen and Bihari, 1998). The sequential failure of organ systems apparently unrelated to the site of the initial insult has been correlated with altered plasma cytokine levels observed in sepsis (Donnelly and Robertson, 1994; Pinsky *et al.*, 1993; Marty *et al.*, 1994).

Because ARF secondary to ischemic or nephrotoxic insults arises from ATN, predominantly to renal proximal tubule cells, replacement of the functions of these cells during the episode of ATN and in conjunction with hemofiltration provides almost full renal replacement therapy. The addition of metabolic activity, such as ammoniogenesis and glutathione reclamation, endocrine activity, such as activation of vitamin D<sub>3</sub> (low levels of which seem to

correlate with high mortality rates in hospitalized patients; Thomas *et al.*, 1998), immunoregulatory support, and cytokine homeostasis may provide additional physiologic replacement activities to change the current natural history of this disease process (Humes, 2000).

Recent experiments investigated whether treatment with the bioartificial kidney would alter the course of ARF and ATN with sepsis in animal models. Mongrel dogs that underwent surgical nephrectomy-induced ARF were treated with continuous venovenous hemofiltration (CVVH) and either a RAD containing cells or an identically prepared sham noncell cartridge. After four hours of therapy, 2 mg/kg intravenous endotoxin was infused over 1 h to simulate gram-negative septic shock. Mean peak levels of an anti-inflammatory cytokine, IL-10, and mean arterial pressures were found to be significantly higher in cell-treated animals (Fissell *et al.*, 2002).

To further assess the effect of the bioartificial kidney in ARF with bacterial sepsis, dogs were nephrectomized and 48 hours later administered intraperitoneally with  $3 \times 10^{11}$  *Escherichia coli* cells per kilogram body weight (Fissell *et al.*, 2003). Immediately after bacteria administration, animals were placed in a CVVH circuit with either a RAD with cells or a sham RAD without cells. Cell RAD treatment maintained better cardiovascular performance, as determined by mean arterial blood pressure and cardiac output, for longer

periods than sham RAD therapy. All sham RAD animals expired within 2–10 hours after bacteria administration, whereas all cell RAD-treated animals survived greater than 10 hours. Plasma cytokine levels in the bacteremic animals were assessed. Levels of IL-10, an antiinflammatory cytokine, were significantly elevated in the cell RAD group as compared with the control group. A significant correlation between the rise in plasma IL-10 levels and the decline in mean arterial pressure was observed. The cell RAD maintained renal metabolic activity throughout the septic period (Fissell *et al.*, 2003).

In another study, pigs with normal kidney function were administered intraperitoneally with  $3 \times 10^{11}$  *E. coli* cells per kilogram body weight. One hour later, animals were placed in a CVVH circuit containing either a RAD with cells or a sham RAD without cells. All animals developed ARF with anuria within 2–4 h after bacteria administration. Cell RAD treatment maintained better cardiovascular performance, as determined by cardiac output and renal blood flow, for longer periods than sham RAD therapy. Consistently, the cell RAD group survived longer than the controls ( $10 \pm 2$  hours versus  $5 \pm 1$  hour, respectively). RAD treatment was associated with significantly lower plasma circulating levels of IL-6, a proinflammatory cytokine, and interferon- $\gamma$ . These data demonstrate that septic shock results in early ARF and that RAD treatment in a bioartificial kidney circuit improves cardiovascular performance associated with changes in cytokine profiles and confers a significant survival advantage (Humes *et al.*, 2003).

### Phase I and II Clinical Experience with a Human Renal Tubule-Assist Device

With these encouraging preclinical data, the Food and Drug Administration approved an Investigational New Drug application to study the RAD containing human cells in patients with ATN receiving CVVH. Human kidney cells were isolated from kidneys donated for cadaveric transplantation but found unsuitable for such purpose because of anatomic or fibrotic defects. The initial results in the first 10 treated patients in this Phase I/II trial demonstrated that this experimental treatment can be delivered safely under study protocol guidelines in this critically ill patient population for up to 24 hours when used in conjunction with CVVH (Humes *et al.*, 2004). These data also indicate that the RAD maintains and exhibits viability, durability, and functionality in this *ex vivo* clinical setting. Cardiovascular stability of the patients was maintained, and increased native renal function, as determined by elevated urine outputs, temporally correlated with RAD treatment, a finding that requires additional study. The isolated and expanded human cells also demonstrated differentiated metabolic and endocrinologic activity in this *ex vivo* treatment. Glutathione degradation and endocrinologic conversion of 25-OH-D<sub>3</sub> to 1,25-(OH)<sub>2</sub>-D<sub>3</sub> by the RAD tubule cells were demonstrated.

All 10 patients were critically ill with ARF and multi-organ dysfunction syndrome, with predicted hospital mortality rates between 80% and 95%. One patient expired within 12 hours after RAD treatment because of his family's request to withdraw ventilatory life support. Another patient expired after a surgical catastrophe (toxic megacolon) required discontinuation of RAD treatment after only 12 hours. Of the remaining eight patients, six survived past 28 days with renal function recovery. The other two patients died from nonrecoverable complications unrelated to RAD therapy and ARF, including fungal pericarditis and vancomycin-resistant enterococcus septicemia in one patient and ischemic colitis with bowel perforations in the other patient. Plasma cytokine levels suggest that RAD therapy produces dynamic and individualized responses in patients, depending on their unique pathophysiologic conditions. For the subset of patients who had excessive proinflammatory levels, RAD treatment resulted in significant declines in granulocyte-colony stimulating factor (G-CSF), IL-6, IL-10, and especially IL-6/IL-10 ratios, suggesting a greater decline in IL-6 relative to IL-10 levels and a less proinflammatory state. These results were encouraging and led to an FDA-approved, randomized, controlled, open-label Phase II investigation, which was recently completed at 10 clinical sites to assess the safety and early efficacy of this cell therapy approach. The results have been equally as compelling as the Phase I/II trial results. Renal cell therapy improved the 28-day mortality rate from 61% in the conventional CVVH-treated control group to 33% in the RAD-treated group (Tumlin *et al.*, 2005).

### Bioartificial Kidney in End-Stage Renal Disease

A bioartificial kidney for long-term use in ESRD, similar to short-term use in ARF, would integrate tubular cell therapy and the filtration function of a hemofilter. Although all ESRD patients could conceivably benefit from a bioartificial kidney, patients in the inflammatory stage of this disease would likely benefit most and will be the target population for clinical study in the near future. For this patient population, however, there are obvious limitations in using an extracorporeal RAD connected to a hemofiltration circuit. Whereas cell therapy, as in ARF, currently can be administered only intermittently, a bioartificial kidney suitable for long-term use in ESRD patients ideally would be capable of performing continuously, like the native kidney, to reduce risks from fluctuations in volume status, electrolytes, and solute concentrations and to maintain acid–base and uremic toxin regulation. These additional functions require the eventual design and manufacture of a compact implantable bioartificial kidney incorporating a RAD capable of self-monitoring and self-repair. The advent of silicon bulk and surface micromachining offers hope for the development of such a device. These technologies allow the fabrication of pores, beams, gears, and pressure sensors and the patterned deposition of cells in engineered microenvironments and

nanoenvironments. Surface micromachining has been used to provide capillary-like conduits for blood flow in hepatocyte tissue cultures, and micropatterning has been used to control cell growth and differentiation (Kaihara *et al.*, 2000; Chen *et al.*, 1998). Clinicians look forward to the possible use of these emerging technologies in the manufacture of a bioartificial kidney for universal, optimal renal replacement therapy for ESRD patients.

### Cell Sourcing

A key critical hurdle for any bioartificial organ program, including kidney replacement, is identifying a robust cell source for the replacement device. In this regard, a specific cell-based therapy requires several important methodologic choices and the solution of a number of technological problems. For cell-based therapies, cells need to be expanded in large quantities while maintaining uniformity in activity and being pathogen free. Current approaches to ensure robust cell expansion and uniformity requirements are dependent on either stem/progenitor cells or transformed cells. The use of human embryonic stem (ES) cells versus adult stem cells is under rigorous societal debate, with the current political environment strongly favoring adult stem cell processes (Brower, 1999; Wertz, 2002). The plasticity of adult stem cells to transdifferentiate from one lineage pathway to another is also under careful scientific scrutiny. The early support for stem cell plasticity appears to be questioned by recent reports demonstrating stem cell fusion with tissue-specific differentiated cells, resulting in polyploidy rather than true stem cell transdifferentiation with normal diploid chromosomal numbers (Terada *et al.*, 2002; Wang *et al.*, 2003; Vassilopoulos *et al.*, 2003). The ability of bone marrow stem cells to differentiate into a variety of cell types within the kidney, including glomerular vascular and tubular elements, has been demonstrated (Brodie and Humes, 2005). These reports, however, demonstrate highly variable engraftment rates and inconsistent phenotypic differentiation. The issue of cell fusion in these experiments has not been addressed. Current cell-based approaches, therefore, are directed toward utilizing adult tissue-specific stem cell expansion, but the potential use of ES cells is also being aggressively pursued.

The utilization of transformed cells, including applications to deliver a gene product with gene therapy, has recently come under intense scrutiny due to safety concerns. The autologous transplantation of genetically modified hematopoietic stem cells in children with adenosine deaminase deficiency, which leads to severe immunodeficiency, resulted in the development of acute leukemia in some of the patients due to genetic integration of the vector in the hematopoietic stem cells (Hacein-Bey-Abina *et al.*, 2003). The ability to retrieve or deactivate these transformed cells following cell implantation is required to mitigate this high risk. Even the use of nontransformed cells may have safety concerns. Implantation of nerve cells in patients with

Parkinson's disease leads to a high rate of severe and uncontrollable dyskinesic activity (Dunnett *et al.*, 2001); implantation of myoblasts into the heart has resulted in high rates of cardiac arrhythmias (Menasché *et al.*, 2003).

A choice between autologous and nonautologous human cells is also critical in the formulation of a cell-based application. Nonautologous cells must overcome natural host immunologic rejection processes. Since most indications preclude the use of immunosuppressant drugs to accommodate the discordant cell implant, immunoprotection of nonautologous cells has been approached with microencapsulation techniques using ultrathin synthetic membranes to prevent entry of antibodies and immunocompetent cells of the host. Implantation of cellular microcapsules has had limited success because of poor long-term functional performance secondary to progressive loss of cell viability (Orive *et al.*, 2003). Success with short-term cell therapy utilizing hollow-fiber bioreactors in an extracorporeal blood perfusion circuit for organ replacement therapy in acute disorders, including ATN, has been more forthcoming (Humes *et al.*, 1999a; Fissell *et al.*, 2003). The use of autologous cells, although overcoming the immunologic barrier, has its own set of problems. Autologous approaches require obtaining the patient's own cells, expanding them *in vitro* in large quantities over several weeks, and then reintroducing the cells in a site-specific manner. Thus, each treatment is an individualized and nonscalable process with substantial logistical and regulatory hurdles, including maintenance of the uniform quality of cells, avoidance of introduced pathogens during cell processing, and potential retrievability after implantation.

A final technologic hurdle for cell-based therapies is the maintenance of cell viability during long-term implantation. Maintenance of cell function depends on adequate nutrient and oxygen delivery to the cellular implant (Avgoustiniatos and Colton, 1997). Creative approaches to induce and maintain formation of a neovascular capillary bed in and around the cell implant with various drug-delivery and cell scaffold formulations have been demonstrated experimentally but have not yet been successfully translated to the clinic (Richardson *et al.*, 2001). An intravascular cell encapsulation implant approach looks promising but requires further experimentation to determine its successful implementation (Humes, 1998).

Although cell-based therapy has substantial technological, regulatory, and ethical barriers, the potential to develop innovative treatments for a large number of clinical disorders, including acute and chronic renal diseases, is expanding rapidly. Progress in this field is highly dependent on an interdisciplinary approach at the interface of a number of scientific disciplines. This approach is at times empiric rather than reductive in nature, without full understanding of the manner in which cells may alter the complex pathophysiology of a systemic disorder. This limitation should not preclude continued efforts in this field. In fact, this empiric

approach may result in unanticipated insights into basic biology, similar to those obtained in immunology as the field of human solid organ transplantation evolved. Cell

therapy has the potential creatively to leverage nature's ability to provide new and much needed treatments to patients with acute and chronic diseases.

### I. INTRODUCTION

There is a severe shortage of donor tissues and organs that is worsening yearly, given the aging population. Currently, patients suffering from diseased and injured organs are treated with transplanted organs or cells. Tissue-engineering techniques are being investigated for the replacement of absent or deficient genitourinary structures, including urethra, bladder, male and female genital tissues, ureter, and renal structures. The goal of tissue engineering is to develop biologic substitutes that can restore and maintain normal function.

This chapter reviews recent advances in regenerative medicine and describes applications of new technologies to treat the genitourinary system, including reconstruction of the patient's organs with autologous cells. This approach allows lost tissue function to be restored or replaced with limited complications due to rejection or the inherently different functional parameters of replacement tissues currently used. Most of the effort expended to engineer genitourinary tissues has occurred within the last decade. Before these engineering techniques can be applied to humans, further studies need to be performed in many of the tissues described in this chapter.

The genitourinary system may be exposed to a variety of possible injuries from the time the fetus develops. Individuals may suffer from congenital disorders, cancer, trauma, infection, inflammation, iatrogenic injuries, or

other conditions that may lead to genitourinary organ damage or loss and necessitate eventual reconstruction. Whenever there is a lack of native urologic tissue, reconstruction may be performed with native nonurologic tissues (skin, gastrointestinal segments, or mucosa from multiple body sites), homologous tissues (cadaver fascia, cadaver or donor kidney), heterologous tissues (bovine collagen), or artificial materials (silicone, polyurethane, Teflon). The tissues used for reconstruction may lead to complications because of their inherently different functional parameters. In most cases, the replacement of lost or deficient tissues with functionally equivalent tissues would improve the outcome for these patients. This goal may be attainable with the use of tissue-engineering techniques.

### II. RECONSTITUTION STRATEGIES

The goal of tissue engineering is to develop biologic substitutes that can restore and maintain normal function. Tissue engineering may involve matrices alone, wherein the body's natural ability to regenerate is used to orient or direct new tissue growth, or it may use matrices with cells. When cells are used for tissue engineering, donor tissue (heterologous, allogeneic, or autologous) is dissociated into individual cells, which are implanted directly into the host or expanded in culture, attached to a support matrix, and reimplanted after expansion. Ideally, this approach allows lost tissue function to be restored or replaced in toto and

with limited complications (Atala *et al.*, 1993a, 1993b, 1994; Atala, 1997, 1999; Cileto *et al.*, 1994; Yoo and Atala, 1997; Fauza *et al.*, 1998; Machluf and Atala, 1998; Yoo *et al.*, 1998; Amiel and Atala, 1999; Kershen and Atala, 1999; Oberpenning *et al.*, 1999; Park *et al.*, 1999).

### III. ROLE OF BIOMATERIALS

Biomaterials in genitourinary-tissue engineering function as an artificial extracellular matrix (ECM) and elicit biologic and mechanical functions of native ECM found in body tissues. Biomaterials facilitate the localization and delivery of cells and/or bioactive factors (such as cell adhesion peptides and growth factors) to desired sites in the body; define a three-dimensional space for the formation of new tissues with appropriate structure; and guide the development of new tissues with appropriate function (Kim and Mooney, 1998). While direct injection of cell suspensions without biomaterial matrices has been used (Brittberg *et al.*, 1994), it is difficult to control the localization of transplanted cells.

The ideal biomaterial should be biocompatible, promote cellular interaction and tissue development, and possess proper mechanical and physical properties. Generally, three classes of biomaterials have been used for engineering of genitourinary tissues: naturally derived materials, such as collagen and alginate; acellular tissue matrices, such as bladder submucosa and small intestinal submucosa; and synthetic polymers, such as polyglycolic acid (PGA), polylactic acid (PLA), and poly(lactic-co-glycolic acid) (PLGA). While naturally derived materials and acellular tissue matrices have the potential advantage of biologic recognition, synthetic polymers can be produced reproducibly on a large scale with controlled properties of strength, degradation rate, and microstructure.

### IV. VASCULARIZATION

A restriction of tissue engineering is that cells cannot be implanted in volumes exceeding 3 mm<sup>3</sup> because of the limitations of nutrition and gas exchange (Folkman and Hochberg, 1973). To achieve the goals of engineering large, complex tissues and possibly internal organs, vascularization of the regenerating cells is essential. Three approaches have been used for vascularization of bioengineered tissue: (1) incorporation of angiogenic factors in the bioengineered tissue; (2) seeding EC with other cell types in the bioengineered tissue; and (3) prevascularization of the matrix prior to cell seeding. Angiogenic growth factors may be incorporated into the bioengineered tissue prior to implantation, in order to attract host capillaries and to enhance neovascularization of the implanted tissue. Many obstacles must be overcome before large entire tissue-engineered solid organs are produced. Recent developments in angiogenesis research may provide important knowledge and essential materials to accomplish this goal.

## V. PROGRESS IN TISSUE ENGINEERING OF UROLOGIC STRUCTURES

Tissue-engineering techniques are currently being investigated for the replacement of lost or deficient genitourinary structures, including urethra, bladder, male and female genital tissues, ureter, and renal structures.

### Urethra

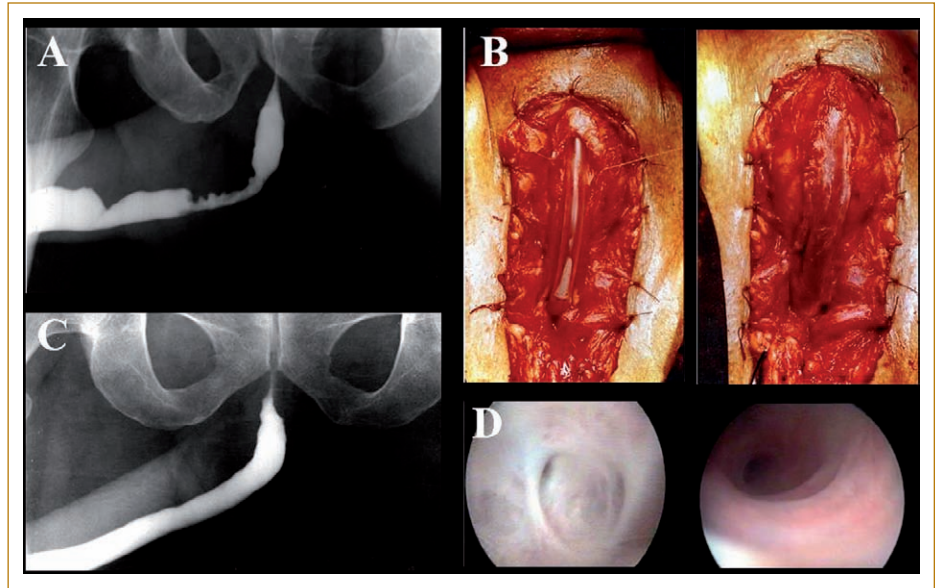

Various strategies have been proposed to regenerate urethral tissue. Woven meshes of PGA, without cells, have been used to reconstruct urethras in dogs (Olsen *et al.*, 1992). PGA has been used as a cell transplantation vehicle to engineer tubular urothelium *in vivo*. Small intestinal submucosa (SIS) without cells was used as an onlay patch graft for urethroplasty in rabbits (Kropp *et al.*, 1998), and a homologous free graft of acellular urethral matrix was also used in a rabbit model (Sievert *et al.*, 2000).

Bladder-derived acellular collagen matrix has proven to be a suitable graft for repairing urethral defects in rabbits. The created neourethras demonstrated a normal urothelial luminal lining and organized muscle bundles (F. Chen *et al.*, 1999). Results were confirmed clinically in a series of patients with a history of failed hypospadias reconstruction whose urethral defects were repaired with human bladder acellular collagen matrices (Fig. 54.1) (Atala *et al.*, 1999). An advantage of this material over nongenital tissue grafts for urethroplasty is that it is “off the shelf,” eliminating the need for additional surgical procedures for graft harvesting and decreasing operative time and potential morbidity from the harvest procedure.

The foregoing techniques, using nonseeded acellular matrices, were successfully applied experimentally and clinically for onlay urethral repairs. However, when tubularized repairs were attempted experimentally, adequate urethral tissue regeneration was not achieved, and complications, such as graft contracture and stricture formation, ensued (le Roux, 2005). Seeded tubularized collagen matrices have performed better than their nonseeded counterparts in animal studies. In a rabbit model, entire urethral segments were resected, and urethroplasties were performed with tubularized collagen matrices, either seeded or nonseeded. The tubularized collagen matrices seeded with autologous cells formed new tissue, which was histologically similar to native urethra. Those without cells led to poor tissue development, fibrosis, and stricture formation.

### Bladder

Gastrointestinal segments are commonly used as tissues for bladder replacement or repair. However, these tissues are designed to absorb specific solutes, and when they come in contact with the urinary tract, multiple complications may ensue, including infection, metabolic disturbances, urolithiasis, perforation, increased mucus production, and malignancy (McDougal, 1992). Because of these problems,

**FIG. 54.1.** Tissue-engineered urethra using a collagen matrix. **(A)** Representative case of a patient with a bulbar stricture. **(B)** Urethral repair. Strictured tissue is excised, preserving the urethral plate on the left side, and matrix is anastomosed to the urethral plate in an onlay fashion on the right. **(C)** Urethrogram six months after repair. **(D)** Cystoscopic view of urethra before surgery on the left side and four months after repair on the right side.

investigators have attempted alternative reconstructive procedures for bladder replacement or repair, such as the use of tissue expansion, seromuscular grafts, matrices for tissue regeneration, and tissue engineering with cell transplantation.

#### Tissue Expansion

A system of progressive dilation for ureters and bladders has been proposed as a method of bladder augmentation but has not yet been attempted clinically (Lailas *et al.*, 1996; Satar *et al.*, 1999). Augmentation cystoplasty performed with the dilated ureteral segment in animals has resulted in increased bladder capacity ranging from 190% to 380% (Lailas *et al.*, 1996). A system progressively to expand native bladder tissue has also been used for augmenting bladder volumes in animals. Within 30 days after progressive dilation, neoreservoir volume was expanded at least 10-fold. Urodynamic studies showed normal compliance in all animals, and microscopic examination of the expanded neoreservoir tissue confirmed a normal histology. A series of immunocytochemical studies demonstrated that the dilated bladder tissue maintained normal phenotypic characteristics (Satar *et al.*, 1999).

#### Seromuscular Grafts

Seromuscular grafts and deepithelialized bowel segments, either alone or over a native urothelium, have also been attempted (Blandy, 1961; Harada *et al.*, 1965). Keeping the urothelium intact avoids complications associated with the use of bowel in continuity with the urinary tract (Blandy, 1961; Harada *et al.*, 1965). An example of this strategy is to combine the techniques of autoaugmentation and enterocystoplasty. An autoaugmentation is performed, and the

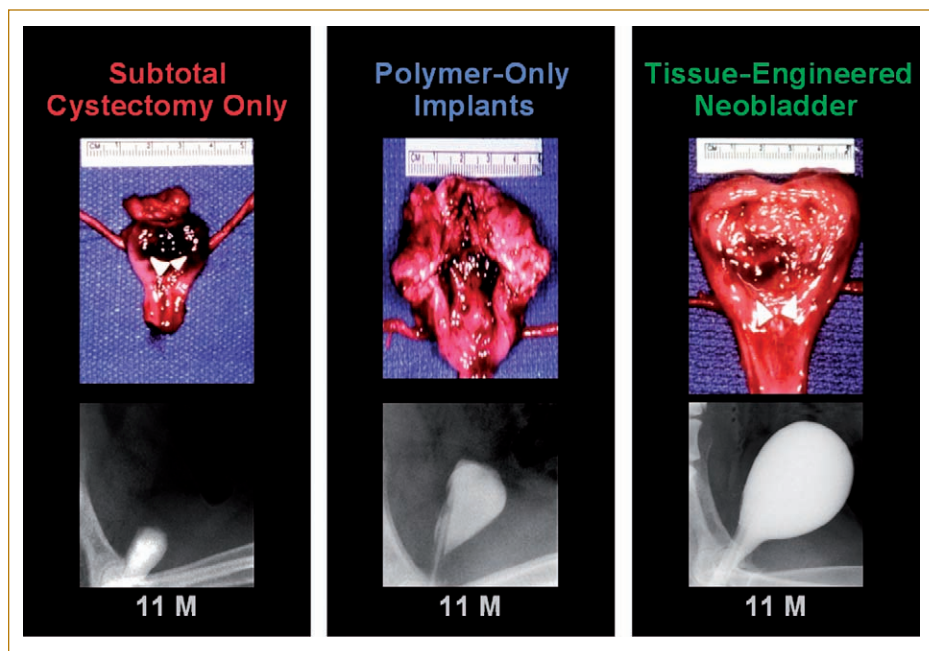

diverticulum is covered with a demucosalized gastric or intestinal segment.

#### Matrices

Nonseeded allogeneic acellular bladder matrices have served as scaffolds for the ingrowth of host bladder wall components. The matrices are prepared by mechanically and chemically removing all cellular components from bladder tissue (Yoo *et al.*, 1998; Probst *et al.*, 1997). The matrices serve as vehicles for partial bladder regeneration, and relevant antigenicity is not evident. For example, SIS (a biodegradable, acellular, xenogeneic collagen-based tissue-matrix graft) was first used in the early 1980s as an acellular matrix for tissue replacement in the vascular field. It has been shown to promote regeneration of a variety of host tissues, including blood vessels and ligaments (Badyalak *et al.*, 1989). Animal studies have shown that the nonseeded SIS matrix used for bladder augmentation can regenerate *in vivo* (Kropp *et al.*, 2004).

In multiple studies using various materials as nonseeded grafts for cystoplasty, the urothelial layer regenerated normally, but the muscle layer, although present, was not fully developed (Yoo *et al.*, 1998; Probst *et al.*, 1997). Often the grafts contracted to 60–70% of their original sizes (Portis *et al.*, 2000), with little increase in bladder capacity or compliance (Landman *et al.*, 2004).

Studies involving acellular matrices that may provide the necessary environment to promote cell migration, growth, and differentiation are being conducted. With continued research, these matrices may have a clinical role in bladder replacement in the future. Recently, bladder regeneration has been shown to be more reliable using SIS derived from the distal ileum (Kropp *et al.*, 2004).

**FIG. 54.2.** Comparison of tissue-engineered neobladders. Gross specimens and cystograms at 11 months of the cystectomy-only, nonseeded controls, and cell-seeded tissue-engineered bladder replacements. The cystectomy-only bladder had a capacity of 22% of the preoperative value and a decrease in bladder compliance to 10% of the preoperative value. The nonseeded controls showed significant scarring, with a capacity of 46% of the preoperative value and a decrease in bladder compliance to 42% of the preoperative value. An average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue-engineered bladder replacements, and the compliance showed almost no difference from preoperative values, which were measured when the native bladder was present (106%).

### Cell Transplantation

Cell-seeded allogeneic acellular bladder matrices have been used for bladder augmentation in dogs. Trigone-sparing cystectomy was performed in dogs randomly assigned to one of three groups. One group underwent closure of the trigone without a reconstructive procedure; another underwent reconstruction with a nonseeded bladder-shaped biodegradable scaffold; and the last underwent reconstruction using a bladder-shaped biodegradable scaffold that delivered seeded autologous urothelial cells and smooth muscle cells (Oberpenning *et al.*, 1999).

The cystectomy-only and nonseeded controls maintained average bladder capacities of 22% and 46% of preoperative values, respectively, compared with 95% in the cell-seeded tissue-engineered bladder replacements (Fig. 54.2). The subtotal cystectomy reservoirs that were not reconstructed and the polymer-only reconstructed bladders showed a marked decrease in bladder compliance (10% and 42% total compliance). The compliance of the cell-seeded tissue-engineered bladders showed almost no difference from preoperative values, which were measured when the native bladder was present (106%). Histologically, the nonseeded scaffold bladders presented a pattern of normal urothelial cells with a thickened fibrotic submucosa and a thin layer of muscle fibers (Fig. 54.2, middle parcel). The retrieved tissue-engineered bladders showed a normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle (Fig. 54.2, right parcel) (Oberpenning *et al.*, 1999). Preliminary clinical trials for the application of this technology have been performed and are under evaluation.

### Genital Tissues

Tissue-engineering techniques have been used to reconstruct male and female genital tissues.

#### Corporal Smooth Muscle

Because one of the major components of the phallus is corporal smooth muscle, the creation of autologous functional and structural corporal tissue *de novo* would be beneficial. To examine functional parameters of engineered corpora, acellular corporal collagen matrices were obtained from donor rabbit penis, and autologous corpus cavernosal smooth muscle and endothelial cells were harvested, expanded, and seeded on the matrices. The entire rabbit corpora was removed and replaced with engineered scaffolds. The experimental corporal bodies demonstrated intact structural integrity by cavernosography and showed similar pressure by cavernosometry when compared with normal controls. The control rabbits (without cells) failed to show normal erectile function throughout the study. Mating activity in the animals with the engineered corpora appeared normal by one month after implantation. The presence of sperm was confirmed during mating and was present in all the rabbits with the engineered corpora. The female rabbits mated with the animals implanted with engineered corpora and also conceived and delivered healthy pups. Animals implanted with the matrix alone were unable to demonstrate normal mating activity and failed to ejaculate into the vagina (K. L. Chen *et al.*, 2005).

#### Engineered Penile Prostheses

Although silicone is an accepted biomaterial for penile prostheses, biocompatibility remains a concern (Thomalla

*et al.*, 1987). The use of a natural prosthesis composed of autologous cells may be advantageous.

A recent study using an autologous system investigated the feasibility of applying the engineered cartilage rods *in situ* (Yoo *et al.*, 1999). Autologous chondrocytes harvested from rabbit ear were grown and expanded in culture. The cells were seeded onto biodegradable poly-L-lactic acid-coated PGA polymer rods and implanted into the corporal spaces of rabbits. Examination at retrieval one month later showed the presence of well-formed, milky-white cartilage structures within the corpora. All polymers were fully degraded by two months. There was no evidence of erosion or infection in any of the implantation sites.

Subsequent studies assessed the long-term functionality of the cartilage penile rods *in vivo* (Yoo *et al.*, 1999). To date, the animals have done well and can copulate and impregnate their female partners without problems.

### Female Genital Tissues

Congenital malformations of the uterus may have profound implications clinically. Patients with cloacal exstrophy or intersex disorders may not have sufficient uterine tissue for future reproduction.

We investigated the possibility of engineering functional uterine tissue using autologous cells (Wang *et al.*, 2003). Autologous rabbit uterine smooth muscle and epithelial cells were harvested and then grown and expanded in culture. These cells were seeded onto preconfigured uterine-shaped biodegradable polymer scaffolds, which were then used for subtotal uterine tissue replacement in the corresponding autologous animals. Upon retrieval six months after implantation, histological, immunocytochemical, and Western blot analyses confirmed the presence of normal uterine tissue components. Biomechanical analyses and organ bath studies showed that the functional characteristics of these tissues were similar to those of normal uterine tissue. Breeding studies using these engineered uteri are currently being performed.

Several pathologic conditions, including congenital malformations and malignancy, can adversely affect normal vaginal development or anatomy. Vaginal reconstruction has traditionally been challenging due to the paucity of available native tissue.

Vaginal epithelial and smooth muscle cells of female rabbits were harvested, grown, and expanded in culture. The cells were seeded onto biodegradable polymer scaffolds, which were then implanted into nude mice for up to six weeks. Immunocytochemical, histological, and Western blot analyses confirmed the presence of vaginal tissue phenotypes. Electrical field stimulation studies in the tissue-engineered constructs showed similar functional properties to those of normal vaginal tissue. When these constructs were used for autologous total vaginal replacement, patent vaginal structures were noted in the tissue-engineered spec-

imens, while the nonseeded structures were noted to be stenotic.

### Ureter

Ureteral nonseeded matrices have been used as a scaffold for the ingrowth of ureteral tissue in rats. On implantation, the acellular matrices promoted the regeneration of the ureteral wall components (Dahms *et al.*, 1997). In a more recent study, nonseeded ureteral collagen acellular matrices were tabularized, but attempts to use them to replace 3-cm segments of canine ureters were unsuccessful (Osman *et al.*, 2004).

Cell-seeded biodegradable polymer scaffolds have been used with more success to reconstruct ureteral tissues. In one study, urothelial and smooth muscle cells isolated from bladders and expanded *in vitro* were seeded onto PGA scaffolds with tubular configurations and implanted subcutaneously into athymic mice. After implantation, the urothelial cells proliferated to form a multilayered luminal lining of tubular structures, while the smooth muscle cells organized into multilayered structures surrounding the urothelial cells. Abundant angiogenesis was evident. Polymer scaffold degradation resulted in the eventual formation of natural urothelial tissues. This approach has also been used to replace ureters in dogs (Yoo *et al.*, 1995).

### Renal Structures

Due to its complex structure and function, the kidney is possibly the most challenging organ in the genitourinary system to reconstruct using tissue-engineering techniques. However, concepts for a bioartificial kidney are emerging. Some investigators are pursuing the replacement of isolated kidney function parameters with the use of extracorporeal units, while others are working toward the replacement of total renal function by tissue-engineered bioartificial structures.

### Ex Vivo Renal Units

Although dialysis is currently the most prevalent form of renal replacement therapy, the relatively high rates of morbidity and mortality have spurred investigators to seek alternative solutions involving *ex vivo* systems.
